The *symptoms* of rickets possess nothing of a definite character in the earlier stages of the disease. Its approaches are generally stealthy, and at times almost imperceptible. The child, gradually losing its health and spirits, becomes dull and listless, and labors under derangement of the digestive organs, especially flatulence and colicky pains. When craniotabes exists, the child is very fretful, its sleep is disturbed, and it is liable to suffer from spasm of the glottis. After a while, marked emaciation sets in; the muscles are soft and flabby; the abdomen is tympanitic; the skin is dry and sallow; the face looks pale and doughy; the urine is scanty, turbid, and laterititious; and the alvine evacuations are thin, watery, and fetid, there being nearly always considerable diarrhœa. Bronchial catarrh is of frequent occurrence. Dentition advances slowly, and the teeth, of a black, fuliginous aspect, often begin to decay almost as soon as they pierce the gums. The fontanelles and sutures are unnaturally open, the occipital and posterior half of the parietal bones, especially, being thinned, and the seat of depressions or of open spaces from absorption of their plates, the pericranium and dura mater being in contact with each other; and the whole process of ossification is peculiarly slow and imperfect, sometimes, indeed, almost stationary, if not actually retrogressive. As the disease proceeds, the bones grow more and more soft, and, being unable to sustain the weight of the body or to resist the action of the muscles, are at length strangely and frightfully distorted. The head, although abnormally small, is disproportionately large to the size of the face, and is sunk down between the shoulders; the clavicles are bent and extremely salient; the spine is curved in various directions, especially laterally, and diminished in length; the pelvic bones are curved inwards, so as to lessen very materially the corresponding cavity; the ribs, thickened at their point of union with the costal cartilages, are flattened, and the chest, in consequence, is sensibly increased in its antero-posterior diameter, giving it a narrow, pigeon-shaped appearance. The bones of the extremities are shortened, bent, and twisted upon their axes, while their articular ends, or epiphyses, are softened, rarefied, and greatly expanded, thus appearing much larger and more prominent than naturally. If the child has begun to walk, he becomes daily more feeble on his legs: he waddles, trips, falls, and soon returns to his nurse's arms.

In rachitis there is an actual arrest of development of the bones, which, although it pervades the entire skeleton, is always most conspicuous in the lower extremities, the femur, tibia, and fibula being often fully one-third shorter than in the natural state, and also diminished in diameter, except at the epiphyses, which, as already seen, are always unusually large and prominent, especially if the child has been much on his feet. Under such circumstances, the head and neck of the femur are sometimes forced by the weight of the body into a horizontal position below the level of the great trochanter; the individual is bow-legged, and the joints of the knee and ankle suffer great distortion from the weakened and relaxed condition of their ligaments. The flat bones, during the reparative process, become solidified and hypertrophied in their areolar texture, while the long ones are increased in thickness and strength along the concavity of their curvatures, that they may be the better able to support the superincumbent pressure, and resist the effects of muscular action.

The only disease of the bones with which rachitis is at all liable to be confounded is osteomalacia, or softening. The signs of distinction, however, are commonly very evident. In the first place, rachitis is an affection of infancy and early childhood, whereas mollescence never occurs until after middle age. Secondly, in rickets the softened and flexible state of the skeleton is only temporary; after a time, a process of repair is set up, and gradually continuing, the affected tissues become at length more firm and compact than they are in the natural state; in osteomalacia, on the contrary, the disease, once be-

gun, generally progresses until the patient is worn out by his suffering, no attempt being usually made at restoration. Thirdly, in rachitis there is no material alteration in the urine, whereas in mollescence this fluid is always loaded with a large quantity of earthy salts, the kidneys taking on a vicarious action, and so carrying off the material destined for the supply of the bones. Fourthly, in rickets there is an actual arrest of development, in consequence of which the bones remain disproportionately short, thin, and dwarfish; in softening, on the contrary, the affected pieces retain their normal shape, although they are so changed in their consistence that they may readily be cut and bent in almost any direction. Lastly, in rachitis one of the earliest symptoms, as originally pointed out by Elsässer, and fully confirmed by Vogel, is the existence, on the posterior surface of the skull, of little depressions, pits, or hollows, varying in size from a linseed to that of a bean, easily detectable by the tips of the fingers, and having a soft, elastic feel, not unlike cartridge paper. In osteomalacia no such occurrence is found.

The *prognosis* of rachitis is generally unfavorable, few persons recovering without permanent deformity. In regard to the danger to life, it is commonly in proportion to the number of bones affected, the rapid progress of the complaint, and the age of the subject. Very young children are more liable to die of it than those who are more advanced in years, and those who are born of scrofulous or syphilitic parents than those who come into the world under more happy auspices. The duration of the disease is extremely variable; very tardy at one time, very rapid at another. In general, even under the most favorable circumstances, several years elapse before complete recovery occurs. The progress of the cure is often fatally arrested by some intercurrent malady, as measles, scarlatina, smallpox, or cholera. The longer recovery is postponed, the greater will be the danger of serious deformity. The duration of life is not necessarily shortened in persons who get well of rickets, as cases have occurred in which they attained the age of sixty, seventy, or even seventy-five.

Treatment.—In the treatment of rachitis active measures are out of the question. The chief reliance must be upon a properly regulated regimen and the use of tonics, with a view of invigorating the general system, and of improving the condition of the blood, which is always materially altered in its properties. Whatever, therefore, has a tendency to strengthen the patient, and to enrich the circulating mass, must prove indirectly beneficial in removing the disease, and should claim serious consideration in every case.

The diet should be mild and nutritious, comprising an adequate amount of nourishment in the smallest possible space, so as not to oppress the stomach and create flatulence and acidity. The best article is, of course, the mother's milk, or, when this is insufficient or unwholesome, fresh cow's milk, or, better still, the milk of the ass, which is now so much used in some of the larger cities of continental Europe, and which approaches nearer, in its composition, to human milk than that of any other animal. If the teeth are properly developed, a small amount of animal food will be useful, especially fat bacon, well boiled, and not too salt, with good stale bread, and a little mashed potato. The body should be washed at least twice a day with salt water, followed by dry friction, or rubbed with a moderately stiff salt towel; and, if the system is not too much reduced, cool or cold bathing will be found highly invigorating. Frequent exposure of the little patient to the fresh air, and exercise suited to his age and strength, are to be rigidly enforced. The secretions are improved by alteratives, especially blue mass and mercury with chalk, while the bowels are kept soluble with rhubarb, magnesia, or oil. Acidity is allayed by the alkalies, as lime water, soda, or potassa.

Tonic medicines, particularly quinine and iron, given in small doses, and long continued, with an occasional intermission for a few days, are always imperatively indicated, and there are few cases which are not promptly benefited by their exhibition, especially in the early stages of the disease, although they are nearly equally useful throughout its entire progress. The mineral acids, and the tincture of the chloride of iron, are particularly advisable when the disease is associated with a scorbutic condition of the system. Alterative doses of mercury occasionally exercise a salutary influence, especially when the patient labors under the strumous diathesis, the best form being the bichloride, in combination with a small quantity of iodide of potassium, given in syrup of orange peel. The pain, which is often considerable, is controlled with opiates, either alone or conjoined with diaphoretics.

Lately, the phosphates, formerly so much employed in the treatment of rachitis, on the ground that they would tend to supply the deficiency of earthy matter, have again come into vogue, but it remains to be seen whether they really possess any advantage over the

more ordinary tonic remedies, already referred to, or whether, indeed, they are not inferior to them.   Their best form of exhibition is the syrup.

Of all the so-called antirachitic remedies, however, the most valuable, so far as any individual article is concerned, is cod-liver oil, given several times a day, in doses suited to the age and other circumstances of the patient.   Possessing highly nutritive and alterative properties, it is admirably adapted to support the system, to enrich the blood, and to improve the secernent powers, which are so much at fault in rachitis.   It may be administered either alone or in union with some of the more important tonics above mentioned.

The mattress upon which the child lies should be perfectly free from hollows or depressions, it being a matter of the first moment that the head, trunk, and limbs should rest upon the same plane.   As soon as softening occurs, support must be afforded to the weakened structures by appropriate mechanical appliances.   The erect posture and progression must be interdicted until the bones are sufficiently strong and firm to bear the weight of the body.

The angular deformity left after recovery from this disease is not only very unseemly, but often a serious impediment to progression, and, therefore, demands surgical interference.   When the bones are still soft, the object may generally be attained by forcible extension, performed in a direction opposite to the projection, with the precaution of preventing separation of the epiphyseal connections.   When the reverse is the case, subcutaneous osteotomy must be performed, the division, as stated in the second volume, being effected by means of a saw, trephine, chisel, or dentist's drill, and rectification produced by suitable apparatus, or the use of the plaster bandage.

SECT. XII.—FRAGILITY.

Fragility of the osseous tissue is one of those affections which are to be regarded rather as an effect of disease than as a disease itself.   It consists, as the name implies, in a peculiar brittleness of the bones, in which, especially in its more advanced stages, their substance is so completely changed in its character as to give way under the most trivial circumstances.   All the bones are liable to this morbid brittleness, and cases occur, although rarely, where it literally pervades the whole skeleton.   In 1857, the body of a female, supposed to be upwards of seventy years old, was brought into the dissecting rooms of the Jefferson Medical College, with upwards of eighty fractures, received a few days before in a fall from a third story window upon the pavement below.   Nearly all the ribs, several of the vertebræ, and a number of the long bones, were broken, and signs of former fractures existed in the humerus, thigh, scapula, and other pieces.   Devergie examined the body of a woman who died under symptoms of fragility, in whose skeleton there were not less than eighty-three fractures.   The late Professor William Gibson met with a young man, whom I also saw many years ago, the bones of whose extremities were repeatedly broken by the most trivial accidents.   The clavicles had suffered still more frequently, having been fractured altogether eight times.   This universal fragility of the osseous tissue occasionally occurs at a very early period; sometimes, indeed, even in the fœtus in the womb.   Chaussier met with a remarkable example of this kind, where the long bones had experienced not less than one hundred and thirteen fractures, some being perfectly consolidated, thus showing that they had taken place some time previously, while the rest were either recent or had partially united.   The child survived its birth only twenty-four hours.   General fragility, however, is a comparatively rare affection; usually the disease is limited to particular bones; or, still more commonly, to particular portions of a bone; and those which are most prone to suffer are the head and neck of the femur, the ribs, sternum, radius, ulna, clavicle, and the superior extremity of the humerus.

When the affection exists in its highest degree, the slightest accident is frequently sufficient to produce fracture, as a severe fit of coughing, kneeling upon a hard floor, or turning round in bed.   Sometimes, indeed, the fragility is so great that the individual cannot be touched rudely without the occurrence of the injury.   Of this description was the memorable case of the woman, recorded by Saviard, who could not be moved about in bed without breaking some of her bones.   After a confinement of six months she died, when it was found that she had had fractures in all the long bones of the extremities, as well as of the clavicles, ribs, vertebræ, and pelvis, many of the pieces being so brittle that they could not be handled without crumbling into fragments, similar to old, dry bark.

Fragility of the bones usually comes on without any assignable *causes*, and the general

health not unfrequently remains good until long after it has made its appearance. In most cases, if not in all, it is merely symptomatic of some other disease, particularly of rheumatism, gout, syphilis, scrofula, and scurvy, attended with an altered and impoverished state of the blood, and impairment of the assimilative powers. The bones themselves are very much in the condition in which they are in osteomalacia, that is, they are more or less softened by the removal of their earthy matter, and often so completely saturated with fat as to render them unfit for preparations. On the other hand, however, they are sometimes remarkably dry and brittle. These facts show that their intimate structure undergoes some important anatomical change, the immediate result, apparently, of inflammation. What tends to support this view of the nature of the affection is the circumstance that, long before the bones manifest any disposition to break, the patient is harassed with severe pains, deep-seated, fixed, and referred to particular portions of the skeleton, and that, upon dissection, the diseased parts are generally found to be extremely vascular, their areolar tissue being profoundly injected and infiltrated with bloody matter, while the periosteum is very thick, spongy, and highly congested.

Fragility of the bones is one of the usual concomitants of old age. As life advances, their vascularity sensibly diminishes, many of the vessels shrinking, and becoming finally entirely obliterated. It is owing to this circumstance that old persons, especially females after the fifty-fifth year, are so much more liable to fracture than to dislocation, the part most prone to yield being the neck of the femur within the capsular ligament, whose areolar tissue is often astonishingly rarefied, while the compact is hardly as thick as ordinary letter paper. A fatty and brittle state of the bones is not uncommonly an effect of general paralysis.

This disease is sometimes observed in several members of the same family. In an instance related by Dr. Pauli, of Landau, it was distinctly traceable through three generations on the father's side. All the grandchildren, five in number, had each had several fractures, one as many as five, in the bones of the extremities, mostly as the result of inconsiderable injury. They were all remarkably healthy, without any evidence in any of them of a scrofulous taint of the system.

An instance of a similar kind was recently communicated to me by Dr. H. L. Battle, of Wadley, Georgia. Of a family of eleven children five, all boys, have inherited this peculiarity, evidently through the mother's side, although she has never suffered from fractures. She is affected, however, with curvature of the spine, and her father and several of her brothers and sisters have fragility of their bones. All the unsound children resemble their mother in complexion and in the color of their eyes. The oldest, now twenty-four years of age, has had sixty-four fractures; the next, two years younger, thirty-four; the third, aged thirteen, thirty; the fourth, eleven years, ten; and the fifth, two years old, two. All the fractures occurred in the femur, generally from very slight causes. The other children, all girls, strikingly resemble their father, and enjoy excellent health. Under proper treatment the fractures always unite very promptly, and, what is singular, none of these persons have, at any time, experienced any severe pain, so common under such circumstances.

There are, unfortunately, no reliable *symptoms* of this affection. On this account it is usually overlooked until it has reached its highest degree of development, when it is always incurable. In general, the person is laboring under severe pain, which, as it is usually regarded as of a gouty, rheumatic, or syphilitic character, is rarely, if ever, referred to its proper source, until after the occurrence of curvature, or fracture, from causes so slight as to awaken, for the first time, a suspicion of the real nature of the disease. As the disorder progresses, the appetite and strength become impaired, the suffering increases in violence, and the urine is surcharged with earthy constituents, especially phosphate and carbonate of lime. This alteration in the urine is observable at an early period, and in general fragility goes on gradually augmenting down to the time of death, which happens at from six to eighteen months, the patient meanwhile being perfectly bedridden.

There are then only two circumstances that can be at all relied upon as diagnostic of this complaint ; one is the severe and intractable character of the pain, deep-seated, and usually referred to the bones ; the other, the altered condition of the urine, as declared by the presence of an inordinate quantity of earthy matter, especially the phosphatic. When these phenomena coexist, there will be strong reason to conclude that there is serious lesion going on in the skeleton, and this suspicion will be converted into certainty when, superadded to them, there occurs, without any considerable external violence, curvature, fracture, or displacement of some of the bones.

Fragility, like softening, is generally an incurable affection. The only exception, perhaps, to this rule is when it occurs as an effect of the syphilitic or rheumatic poison, but even then it seldom admits of complete relief unless it presents itself in a very circumscribed form. The fragility of old age is always irremediable.

No rational *treatment* has yet been laid down for this disease, nor will it be possible to do so until we shall have more enlightened views of its etiology, pathology, and diagnosis. In all cases strict inquiry should be instituted into its origin, when such remedies should be administered as the result may seem to indicate. A tonic and supporting course, consisting of the different preparations of iron and quinine, and of the syrup of the phosphates, along with cod-liver oil, and vegetable acids, especially the citric, and a well-regulated, nutritious diet, will afford the best chance of relief in the scorbutic diathesis. Iodide of potassium and bichloride of mercury should be given in the syphilitic variety of the disorder; while in the gouty and rheumatic forms, colchicum may, probably, prove beneficial. In Dr. Battle's cases, above referred to, marked benefit has accrued from a change of vegetable to animal food. To relieve the excessive pain which is so prominent a symptom in the latter stages of the affection, especially when it involves a large portion of the skeleton, anodynes must be given in full and sustained doses. Curvatures and fractures must be treated upon general principles. In most cases union occurs very promptly; sometimes, however, it is very tedious, and now and then the parts refuse to heal, despite the best directed efforts of the surgeon.

SECT. XIII.—ATROPHY.

Atrophy of the osseous tissue is characterized by the partial absorption of its elementary constituents, as is evinced by its lightness and porosity. It may occur in any portion of the skeleton, but the long bones are oftener affected than the short or flat. Like hypertrophy, it may be partial or general; that is, it may involve an entire piece, or be limited to a particular part of it. Atrophy, moreover, may be concentric or eccentric. In the former variety the bone is diminished in its diameter; in the latter it retains its original size, but is reduced in weight, and rarefied in structure. The principal causes are, protracted pressure, chronic inflammation, deficient nervous influence, and insufficient supply of arterial blood.

α. The influence of steadily exerted *pressure*, in producing atrophy of the osseous tissue, is well exemplified in the cranial bones in tumors of the dura mater; in the sternum and dorsal vertebræ in aneurism of the aorta; and in the ribs in carcinoma of the mammary gland. In all these instances the compact substance is reduced to a thin, translucent plate, while the spongy texture is either wholly destroyed, or worn down to a few slender shreds. The immediate cause of the wasting process here is absorption, acting simultaneously and equally upon the animal and earthy constituents.

β. Atrophy from *chronic inflammation* is probably infrequent. One of the best specimens of it that I have ever seen occurred in a colored woman, who died of pulmonary phthisis at the age of forty. The body was much emaciated, and all the long bones were remarkably reduced in weight, although they had experienced no change in their external configuration. The compact substance was wasted to a mere shell, scarcely thicker than common wrapping paper, while the cells of the spongy texture were increased many times beyond the natural size. The medullary canal was much enlarged, and filled with a greasy reddish substance, not unlike fresh adipocire. These appearances are well shown in fig. 395, and afford a beautiful illustration of the eccentric form of atrophy.

Fig. 395.

Atrophy of Bone.

Atrophy is sometimes the result of local injury, as a blow, wound, or contusion. The wasting in this case may be limited to the site of the original mischief, or it may extend to the entire bone, which, however, is uncommon. In what manner such an injury operates, whether through the agency of inflammatory irritation or otherwise, in giving rise to atrophy, is unknown.

A bad form of atrophy, often followed by permanent lameness, occasionally occurs in the neck of the femur, as well as in other portions of the skeleton, from what is called interstitial absorption of the osseous tissue. It is generally caused by external injury, but may also arise from attacks of cold, gout, rheumatism, and syphilis. The
osseous structure wastes under its influence, and is frequently followed by important alterations in the conformation and direction of the affected bone.

γ. Deficient *nervous* influence is a frequent cause of atrophy both of the osseous tissue and of the soft parts. In paralysis of the lower extremities there is usually notable wasting, not only of the muscles, but also of the long bones, which are greatly reduced in weight, rarefied in their texture, and diminished in size. Atrophy of the osseous tissue is occasionally dependent upon general paralysis, especially if long continued.

δ. The effect of a diminished supply of *blood* in inducing atrophy of bone is sometimes very conspicuous in old fractures. In such injuries there is often considerable wasting of

Fig. 396.   Fig. 397.
Atrophy of connective Structure
of the Thigh-bone.

Advanced stage of senile Atrophy
of the Thigh-bone.

the osseous tissue, simply from obliteration of the nutrient artery by the pressure of the callus. The atrophy is always eccentric, and is usually limited to one-third, one-half, or two-thirds of the affected bone, according to the seat of the original injury; or, more properly speaking, the quantity of the new matter, and the extent of the vascular obliteration.

ε. Finally, there is what is termed *senile atrophy*. In old age, the bones are rendered light, porous, and brittle; the compact substance is reduced to a mere parchment-like shell, while the areolar texture is remarkably rarefied or expanded; the muscular prominences are diminished in size; the animal matter is partially absorbed; and many of the vessels are obliterated. These changes are nowhere more conspicuous than in the neck of the femur, which, in consequence, often breaks from the most trifling causes, and which, after this occurrence, is seldom, if ever, repaired by osseous matter. Fig. 396 is a section of a well-marked specimen of this kind; the internal structure is very much rarefied; and the head of the bone, flattened and expanded, is approximated to the shaft, from the partial absorption of its neck. Fig. 397 exhibits the affection in a still more advanced stage with porcellanous deposits. Wasting of the alveolar process in edentulous subjects is a beautiful illustration of senile atrophy of bone unaccompanied by disease.

Atrophy of the osseous tissue does not admit of cure. All that the surgeon can do is to amend the general health, when that is at fault, and to remove any local causes of disease when they are found to exist.

SECT. XIV.—HYPERTROPHY.

Hypertrophy of the osseous tissue may be partial or general, as the abnormal growth affects either a portion or the whole of a bone. The latter, however, is very uncommon, except in some of the broad pieces of the skeleton, particularly those of the skull, which,

now and then, present an extraordinary degree of development, being, perhaps, three or four times the natural thickness, and so hard as to render it very difficult to saw them. The diploë is totally obliterated by dense, earthy matter. Similar appearances are sometimes witnessed in the cylindrical bones of the extremities. In an old femur in my private collection, the medullary canal is scarcely large enough to admit a common-sized quill; the whole shaft consists almost entirely of compact substance, in many places more

Fig. 398.

General Hypertrophy, showing the Internal Condition of the Bone.

than six lines in thickness. The bones of the male are always larger and more distinctly developed than those of the female, and the bones of persons who take much exercise than those who are indolent or inactive. By labor, their weight and dimensions increase; their spongy structure diminishes, whilst the compact becomes harder and more dense, and acquires an almost rock-like solidity; the muscular prominences are rendered more conspicuous; in short, everything indicates that they are in a state of general hypertrophy. The osseous tissue usually contains its due proportion of animal matter, and on this account does not readily yield under external injury.

Hypertrophy may affect a bone both in length and in thickness. The former occurrence, however, is only possible during the developmental period of bone, for as soon as the osseous tissue has attained its full growth it ceases. An increase in the thickness of a bone, on the contrary, may arise at any time from any cause capable of producing irritation and hyperemia.

Fig. 399.

Hypertrophy involving both the Thickness and Length of the Bone.

Sometimes the hyperostosis affects the entire skeleton, as in a case reported by Dr. J. Ewing Mears, in which the disease was associated with osteoporosis. The patient, a boy fourteen years of age, had died from exhaustion, after having long suffered, as was supposed, from strumous inflammation. The change of structure was most conspicuous in the bones of the extremities, those of the trunk and skull being but slightly affected.

The adjoining cut, fig. 398, from a specimen in my cabinet, is an excellent representation of general hypertrophy of the femur of a man affected with tertiary syphilis. The section of the bone exhibits its interior structure, which is very much condensed throughout, except at the superior extremity, where there are still some remains of the areolar tissue; the medullary canal is entirely obliterated, and the weight of the bone is nearly twice as great as in health. The exterior of the bone is very rough; and the periosteum was greatly thickened and indurated from chronic inflammation.

The annexed sketch, fig. 399, is a specimen of hypertrophy of the bones of the leg and foot, both in thickness and length. It is from a drawing of a preparation in the collection of the late Professor Buchanan, of Nashville. All the bones are much enlarged, increased in weight, and ankylosed at the ankle, tarsal, and metatarsal joints. The interosseous ligament was completely ossified. The foot and leg had been the seat of extensive ulceration, followed by exfoliation from the hypertrophied bones.

General hypertrophy of the bones is usually incurable. It is only, or chiefly, when it depends upon a syphilitic taint of the system that it admits of relief; but as this subject

has already been fully discussed elsewhere, it is not necessary to revert to it here.   Elongation is always irremediable.

SECT. XV.—OSTEOPHYTES.

An osteophyte is an osseous growth, differing from an exostosis in not forming a well-defined tumor, growing, as it does, upon rather than from bone.   It occurs chiefly in middle-aged and elderly subjects, upon the more vascular portion of bone, as its articular extremities, its rough lines, and its sutural cartilages, and is more frequent in the femur, fibula, and vertebræ than in any other pieces of the skeleton.

Fig. 400.

The ordinary osteophyte presents itself in a great variety of forms ; sometimes as a pointed stalactite, or sharp, thorn-like spicule, sometimes as a warty excrescence, sometimes as a lamella several lines in length and thickness, and some-times, again, as a body bearing a close resemblance to a coral. In the vertebræ, an osteophyte occasionally extends like a bridge from one piece to another, tying them firmly together ; and a similar arrangement now and then occurs between the articular extremities of some of the long bones, as between the femur and tibia.   The annexed cut, fig. 400, affords a good illustration of this disease as it sometimes occurs in the lower extremity of the femur.   The whole surface of the bone is roughened by the new growths.

The exciting causes of these osseous formations are not always appreciable.   In general, they are developed under the influence of a gouty, rheumatic, syphilitic, or scorbutic state of the system ; occasionally they are directly traceable to the effects of external injury, and cases occur in which

Osteophytes of the Inferior Extremity of the Femur.

they succeed to caries or necrosis.   Immense numbers of osteophytes are sometimes seen in osseous tumors, especially the fibrous and sarcomatous.   The immediate cause of the disease is inflammation, attended with a deposit of lymph, which is gradually converted into osseous tissue, similar to the callus of a broken bone.

There are no symptoms by which this disease can be recognized during life, unless the osteophytes are of great size or unusually prominent, when they may occasionally be distinguished by a careful digital examination.   Its progress is generally very tardy, and there is seldom any danger so long as these bodies do not exert any severe pressure upon important structures.

In the treatment of osteophytes, the first object should be to ascertain, if possible, the nature of the exciting cause, for upon a knowledge of this the whole management of the case will necessarily hinge.   A gouty, rheumatic, or syphilitic state of the system should be met in the usual manner.   The inflammatory character of the affection must not be overlooked.   Mercury is indicated in the earlier stages of the disorder.   The most suitable local remedies are tincture of iodine, iodide of lead ointment, leeches, and blisters.

SECT. XVI.—TUMORS.

The bones are liable to sarcoma, osteoma, chondroma, osteoid-chondroma, fibroma, myxoma, angioma, and hydatid cysts.   Primary carcinoma is not observed in the skeleton, although it is quite common as a secondary formation.   Cysts, with the exception of those which occur in the maxillæ in connection with the glandular follicles of the mucous membrane of the antrum, or with impacted and misplaced teeth, or with the periosteum of the fangs, are probably always due to mucoid softening and cystoid degeneration of myeloid, cartilaginous, and myxomatous neoplasms.   The only vascular tumor of the osseous system is aneurism by anastomosis or arterial erectile growth, true aneurism of the arteries of the bones being unknown, the pulsating tumors hitherto classed under that term being merely highly vascular sarcomas.

Neoplasms originate either from the surface or from the interior of the bones.   The superficial, peripheral, or periosteal growths, which are rather the more common, develop from the soft, osteogenic layer of the periosteum, the outer fibrous layer of the membrane constantly regenerating itself to form a limiting capsule for the tumor, as is shown in fig. 401, from S. W. Gross, which represents a peripheral round-celled sarcoma of the humerus.   The bone itself, between which and its investing membrane the mass is seated,
may be entirely normal, sclerosed, more or less absorbed and eroded, or fractured, or it may be the seat of new deposits in the medulla from the extension of the disease along the Haversian canals. The periosteal growths are moreover distinguished by their oval or fusiform outline, or by their pyriform shape, with the base towards the articulation, when they surround the articular extremities of the bones.

The central, endosteal, or myelogenic tumors start in the medulla and in the osteoblastic layer of cells which line the interior of the medullary canal, and they are also surrounded by a capsule which may be entirely bony, as in fig. 402, also from S. W. Gross, represent-

Fig. 401.   Fig. 402.

Periosteal Round-celled Sarcoma   Central Giant-celled Sarcoma of the Head of the Tibia.
of the Humerus.

ing a giant-celled sarcoma of the head of the tibia, but which is usually partly osseous and partly membranous. The bone, in which the neoplasm originates, finally disappears, and as the latter approaches the surface, it induces chronic ossifying periostitis, through which new layers of bone are constantly being produced to encapsule the growth in an osseous case. With the increase of the tissue of the tumor, the same changes occur in the newly formed shell as occurred in the original bone; but as it disappears, new osseous layers are simultaneously formed by the osteoblastic surface of the periosteum, and the deposit of new bone goes on step by step with the absorption of the older layers. In this way a more or less perfect bony capsule is formed around the central tumors, the minute processes concerned in its production being well shown in fig. 403, from Rindfleisch. The central tumors are generally spherical in shape, and, like the periosteal growths, their surface is generally smooth and even.

The majority of the neoplasms of the bones merely push aside and stretch the adjacent tissues; but sarcoma may become diffused and infect the surrounding textures. Fibroma, chondroma, and sarcoma are very liable to calcification and ossification; and sarcoma is frequently highly vascular and the seat of large effusions of blood. When a pulsating tumor is found in connection with a bone, it may be accepted to be a central sarcoma composed either of giant or of round cells.

Of the various degenerations of these growths, particularly the central myeloid and cartilaginous, the most common, as well as the most interesting, is the cystoid, through which cysts or cystoid spaces, both unilocular and multilocular, with fluid, semifluid, fatty, bloody, sanguinolent, or serous contents, are scattered throughout the mass, and sometimes

to so great an extent as to have replaced almost entirely the original structure, thereby giving rise to the term *cystic tumor* of the older writers. Sections of growths which have undergone this retrograde change convey the impression that the specimen is one of true cystic disease of the bones. The cavities are not, however, true cysts, but irregular spaces,

Fig. 403.
Formation of Bony Capsule in Central Tumors.

the walls of which are composed of fibrillated tissue studded with granular fat and drops of oil, or of the fibrous or osseous bands which intersected the original growth. Their origin is due either to liquefaction, or mucoid softening, of the cellular elements which have undergone fatty metamorphosis, or to extravasations of blood in the softened fatty areas from rupture of the enlarged and degenerated vessels. The contents, in the former event, are turbid, opaque, buff-colored, straw-colored, or clear, and, in the latter mode of formation, they consist of blood, coagula, or sanguinolent fluid. The consistence of the contents is variable; sometimes thin, sometimes glutinous, sometimes semisolid, and, finally, again, solid. The amount of fluid is occasionally so great as to give rise to enormous tumors, as in the examples of cystoid chondroma, recorded by Nélaton and Crampton, in which the thigh measured, respectively, six feet, and six feet and a quarter, in circumference.

Cystoid degeneration of neoplasms of the bones is of sufficient importance to give rise to a class of growths, which, as they differ materially from the solid tumors, are entitled to some consideration at this place in regard to their progress, prognosis, and symptoms. Such a division is incorrect from the standpoint of pathological histology, but it is convenient from a clinical point of view, and cannot well be ignored.

Cystic tumors of the bones are most common in young adults and middle-aged subjects; they are seldom met with before puberty, or after fifty; and they generally arise without any assignable cause, although sometimes their origin is directly traceable to the effects of external injury, as a blow, fall, or contusion. The progress of this disease is always slow. In the lower jaw serous cystic growths of six, twelve, and even fifteen years' standing often occur, without any serious disturbance of the general health, or any particular local disorder, save what results from the pressure of the tumor upon the surrounding structures. Neither the cysts, their contents, nor the parts adjacent manifest, as a rule, any tendency to malignancy; but when the tumor is large, it generally exhibits a marked tendency to destroy the bone in which it is located.

The symptoms of cystic disease of the osseous tissue are originally very vague. The first thing that usually attracts attention is a dull, aching pain in some particular bone, as, for example, the jaw, which is often mistaken for toothache, or rheumatism; this gradually increases in severity and frequency, and is at length found to be dependent upon the presence of a hard tumor, or the expansion of a portion of the bone, more or less tender on pressure and motion, but unattended by any discoloration or intumescence of the overlying

textures. The progress of the disease is always tardy, and it often happens that, after having attained considerable development, it remains, to all outward appearance, for some time perfectly stationary. Then, taking a new start, it again increases, and thus it continues, now advancing and now ceasing, until it has, perhaps, acquired the volume of a large orange, or even of a fist. Still, the general health continues good, there is no emaciation, and the countenance is perfectly free from that distressed, anxious, and sallow state which characterizes it in malignant disease. Even the pain is generally comparatively trivial, and if it were not for the mechanical obstruction occasioned by the encroachment of the tumor upon the adjacent parts, the patient would hardly be conscious of being unwell. If the parts be now carefully examined, they will be found to be of unequal consistence, the firmer being incompressible, while the softer ones readily yield under the finger, emitting a peculiar crackling noise not unlike that of dry parchment. When the investing capsule is entirely membranous, the consistence is soft and apparently fluctuating. In the absence of signs of malignancy, pulsation, lividity, and varicose enlargement of the overlying vessels, these circumstances afford the best evidence of the true nature of the disease; but if there is any doubt respecting it, this may generally be promptly dispelled by a resort to the exploring needle, the want of resistance and the escape of serous or sero-sanguinolent fluid determining the diagnosis. The tardy growth of the tumor and the absence of constitutional disorder are, indeed, commonly of themselves sufficient to mark the character of the malady. Between cystic and hydatid affections of the bones no signs of distinction exist, nor is this a matter of importance, as the treatment is essentially similar.

1. SARCOMA.

By far the most important of the tumors of the osseous system, as it constitutes nearly one-half of the neoplasms of the maxillæ, and affects the long bones almost as frequently as all the other morbid growths combined, is sarcoma, which up to comparatively a recent period was described under a great number of different and confusing names. In an elaborate paper on sarcoma of the long bones, published by Dr. S. W. Gross in the American Journal of the Medical Sciences for July and October, 1879, the entire subject has been so exhaustively investigated that its contents have been freely utilized in the following description. The consideration of the disease, as it involves other pieces of the skeleton, will be found in the second volume of this work in its appropriate places.

Sarcomas of the long bones evince a great predilection for their articular extremities, in the spongy substance of which the majority are developed. Whether of central or peripheral origin, their favorite seats are the femur, tibia, humerus, fibula, ulna, and radius. In accordance with their point of departure and histological construction, they may be classified, in the order of their frequency, as central giant-celled, periosteal osteoid, central spindle-celled, periosteal round-celled, central round-celled, and periosteal spindle-celled, the first two varieties constituting nearly 70 per cent. of the entire number. Males are more liable to their occurrence by 17 per cent. than females. The age at which they first appear averages twenty-seven years, 68 per cent. occurring before the thirtieth year, and 32 per cent. after that period, the disease being comparatively uncommon after the age of forty. The period of life at which they manifest themselves appears to be influenced by their seat and structure, the average being twenty-two years for the periosteal osteoid, twenty-three for the periosteal round-celled, twenty-four for the periosteal spindle-celled, twenty-eight for the central round-celled, a fraction above twenty-eight for the giant-celled, and thirty-six for the central spindle-celled. In about one-half of all cases they may be traced to injuries, such as blows, falls, sprains, fractures, and kicks.

With the exception of carcinoma of the soft parts, sarcoma of the bones is the most malignant of all neoplasms; but the lymphatic glands are, as a rule, free from contamination, thereby showing that systemic infection takes place through the blood and not through the lymph channels. Metastatic tumors were discovered, especially in the lungs, lymphatic glands, and other parts of the osseous system, in 46 per cent. of the 165 cases analyzed by Dr. Gross, and they were histologically identical with the primary growth. In the order of their malignity, the sarcomas may be classed as periosteal spindle-celled, periosteal round-celled, periosteal osteoid, central round-celled, central spindle-celled, and central giant-celled, the periosteal tumors being more malignant than the central by 43.5 per cent.

Sarcoma not only evinces a decided tendency to infect the surrounding tissues, but in one example out of every seven and one-third it projects masses into the adjacent joint, as

is represented in fig. 404, from a preparation in my collection, and may even extend along the intraärticular ligaments into the apposed bone. In the majority of these cases, however, the cartilage of incrustation remains intact, and affords a delicate investment for the growth. Invasion of the joints is met with in 18 per cent. of the central and in 7 per cent. of the periosteal tumors; and the possibility of its occurrence should not be lost sight of in selecting the point at which an amputation should be performed for the relief of the disease.

In the absence of minute examination, a pretty accurate idea of the structural nature of these tumors may be formed from their gross appearances. Thus as dark-red or maroon color suggests a giant-celled sarcoma; a firm, glistening, grayish-white tissue is characteristic of fibrous or large spindle-celled growths; and a tint and consistence similar to that of the fœtal brain indicate a round-celled or small spindle-celled tumor, to which the term medullary or encephaloid is applicable, and the assumption will be greatly strengthened if the tissue resembles a recent coagulum, or is interspersed with cavities filled with blood. An admixture of osseous or calcareous masses with soft tissue warrants the diagnosis of an osteoid sarcoma, the nature of the softer portions determining the variety of sarcoma to which the specimen belongs.

The differential diagnosis of these varieties of sarcoma may usually be determined by attention to their affinities and contrasts, which are set forth in the following tables :—

Fig. 404.

Periosteal Spindle-celled Sarcoma, invading the Knee-joint.

Clinical Features of Central Sarcomas.

	Giant-celled.	Spindle-celled.	Round-celled.
Frequency of occurrence	71.42 per cent.	16.32 per cent.	12.24 per cent.
Appear before the 30th year	66.66 "	37.5 "	58.33 "
Seated in the shaft of the long bones	5.71 "	27.27 "	33.33 "
Ushered in by pain	50 "	60 "	75 "
" " swelling	19 "	30 "	25 "
" " " and pain	31 "	10 "	0 "
Pain throughout the disease	40 "	100 "	91 "
Skin variously altered	33 "	40 "	41 "
Subcutaneous veins enlarged	27 "	50 "	41 "
Infection of adjacent tissues	12 "	18 "	66 "
Lymphatic glands tumified or involved	16 "	0 "	25 "
Metastatic deposits	22.72 "	23.07 "	33.33 "
Local recurrence	8 "	20 "	25 "
Pulsation	20 "	12.5 "	33.33 "
Joints invaded	14 "	25 "	25 "
Fracture, spontaneous, or from slight causes	4 "	44 "	50 "

Clinical Features of Periosteal Sarcomas.

	Round-celled.	Spindle-celled.	Osteoid.
Relative frequency	1.40 per cent.	13.43 per cent.	67.16 per cent.
Occur before 30th year	63.63 "	66.66 "	91.66 "
Seated around shaft of the long bones	89 "	55 "	39 "
Ushered in by pain	55 "	85.71 "	62 "
" " swelling	44 "	14.29 "	33 "
" " " and pain	0 "	0 "	4 "
Pain throughout the disease	66 "	100 "	98 "
Skin variously altered	50 "	22.22 "	20 "
Subcutaneous veins enlarged	41 "	33.33 "	31 "
Infection of adjacent tissues	50 "	44 "	40 "
Lymphatic glands tumified or involved	38.46 "	11 "	21 "
Metastatic deposits	66.66 "	100 "	65.62 "
Local recurrence	50 "	60 "	41 "
Pulsation	0 "	0 "	3 "
Joints invaded	15.38 "	0 "	6 "
Fracture, spontaneous, or from slight causes	7 "	11 "	3 "

It will thus be observed that giant-celled tumors, which are the least malignant, occur at an earlier age, and are marked by sympathetic lymphatic involvement, nearly two-thirds as frequently as the round-celled, which are the most pernicious of the central tumors. It is also notable that the lymphatic glands are never enlarged in the central spindle-celled sarcomas, and as this statement is almost true of the same variety developed from the periosteum, it forms an important point in the diagnosis. It will, moreover, be seen that a central tumor occupying the shaft of a bone is far more likely to be round-celled or spindle-celled than giant-celled. Spontaneous fracture and invasion of the joints is far more common in the central than in the periosteal tumors, and are quite characteristic of medullary growths. Enlargement of the subcutaneous veins and alterations of the integument are also more frequent in the central than in the peripheral sarcomas, although the latter occur at an earlier age. Of the various symptoms, one of the most interesting is pulsation, which is observed in one case out of every eight, and which has led certain writers to describe these tumors as aneurisms. It is not met with in any other neoplasm of the bones, and is, therefore, when present, of great diagnostic value. With one exception it has only occurred in the central tumors, and is more common in the round-celled than in the other varieties. A curious fact in regard to pulsation, and it is one that is useful in the discrimination between the sarcomas, is that the chances are three to one that a pulsating sarcoma of the shaft of a long bone is composed of round-cells, and that in no instance is it a myeloid sarcoma: whereas, if the pulsating growth occupies the epiphysis, the chances are ten to one that it belongs to the giant-celled variety.

The only one of the neoplasms of the tubular bones that is liable to occasion errors in diagnosis is chondroma. When compared with central sarcoma, central chondroma is of infrequent occurrence; it is less painful, of slower growth, of firmer consistence, and has a bosselated outline, which is rarely seen in sarcoma unless the capsule is perforated. It is more common in males; never occurs so early or so late in life as sarcoma; does not pulsate, invade the joints, fungate, or give rise to metastatic deposits. Central chondroma, however, in consequence of the cystoid degeneration to which it is so liable, attains a larger volume than sarcoma, and is accompanied in the majority of cases by enlargement of the subcutaneous veins. Periosteal chondroma is relatively more common than periosteal sarcoma. It is far less painful, of slower growth, of denser consistence, and of a nodular outline. It is usually met with in females; does not occur so early in life, and is observed at a more advanced age than sarcoma. The subcutaneous veins are not so liable to enlargement; the integuments evince little disposition to inflame or ulcerate; the tumor does not pulsate, fungate, or invade the joints, or contaminate the glands; and it occasions secondary deposits only one-twentieth as often. In one-third of all cases other portions of the skeleton are simultaneously affected; while multiple growths are only witnessed in sarcoma as the result of infection.

Sarcoma is liable to be confounded with other affections, of which strumous articular osteitis is the most common. White swelling of the knee, for example, usually occurs in scrofulous subjects before the age of fifteen. The pain, which is experienced from the very outset, finally becomes very severe; the skin is tense and glossy; the superficial veins are abnormally prominent; the temperature is elevated; the joint is stiff, resents efforts at motion, and is, moreover, distorted and flexed; puncture gives vent to turbid synovial or purulent fluid; and the swelling does not pulsate, nor does it impart a parchment like crepitation on manipulation. In sarcoma, the movements of the joint are preserved, there is no suffering on motion, and the limb is not fixed in a vicious position. In this affection there is no tendency to the formation of pus; the tumor not infrequently pulsates and affords crepitation on palpation; and spontaneous fracture is not uncommon. White swelling yields to rest, extension, and gentle and equable compression; but sarcoma continues to grow under the employment of these measures, and compression occasions not a little local suffering. The latter affection is not met with at so early an age as white swelling, and it occurs in persons of excellent general health.

The principal features of the sarcomas as a class having thus been considered, the general pathology and diagnosis of the individual tumors demand attention.

1. *Giant-celled Sarcoma.*—Myeloid or giant-celled sarcoma, which invariably occurs as a central growth, and of which a beautiful illustration is afforded by fig. 402, constitutes 42 per cent. of all the sarcomas of the long bones, and has a predilection for the epiphyses of the tibia, femur, and fibula, the shafts being involved in only one example out of every fourteen. It is most common between twenty-one and forty years; increases more slowly than the other sarcomas; is free from pain and tenderness; the skin almost always preserves its mobility and natural tint; the subcutaneous veins are rarely

enlarged; the surrounding tissues are not implicated by extension of the disease; the lymphatic glands are never involved except in 16 per cent. of all cases, and then only as the result of irritation; the joints are invaded in 16 per cent. of all examples; the spherical tumor pulsates in one example out of every five; and the affected bone is rarely broken. The prognosis is comparatively favorable, metastatic tumors developing in only about 23 per cent. of all examples, and local recurrence after amputation or resection being witnessed in one case out of every twelve and a half. In connection with the general dissemination of the disease it is interesting to note that the tumor had undergone calcareous or osseous degeneration, through which it resembled the periosteal osteoid growths, in four-fifths of the cases; while of the cases in which these changes were not present, only one out of fifteen was characterized by secondary growths.

2. *Central Spindle-celled Sarcoma.*—Central spindle-celled sarcoma, which includes many examples of the encephaloid tumors of the older writers, is next to the preceding variety the most common of the myelogenic growths. Rather more than one-fourth of all cases originate in the medulla of the shaft of the long bones, and they appear less frequently in early adult life than myeloid tumors. Its growth is slow, and attended with suffering; the skin is discolored or adherent in 40 per cent., and the veins are enlarged in one-half of all cases. Spontaneous fracture, or fracture from trifling causes, of the affected bone is observed in 44 per cent. of all examples, and is a sign of great diagnostic value. Pulsation and other signs of aneurism are met with in one case out of every eight. The lymphatic glands are never involved; but metastatic tumors form in 23 per cent. of all cases; and local recurrence is observed in one example out of every five, the malignity being, therefore, slightly greater than that of myeloid sarcoma.

3. *Central Round-celled Sarcoma.*—Myelogenic round-celled sarcoma, which includes the alveolar variety of the disease, and which always constitutes medullary tumors, is the least common of the central growths, but forms in the shafts of the tubular bones in the proportion of 33.33 per cent. It occurs, on an average, earlier in life than spindle-celled sarcoma, but at about the same period as giant-celled. Its development is very rapid and is marked by suffering, changes in the skin, enlargement of the veins, infection of the adjacent tissues, invasion of the joints, and fracture of the bone in which it originates. Pulsation is observed in one-third of all examples, and hence a pulsatile growth of the shaft of a long bone may very properly be referred to this variety. The lymphatic glands are enlarged in one-fourth of all cases; metastatic deposits occur in one-third; and repullulation after removal in one-fourth; thus showing that round-celled tumors are the most malignant of the endosteal sarcomas.

4. *Periosteal Spindle-celled Sarcoma.*—Peripheral spindle-celled sarcoma surrounds the epiphyses more frequently than the shafts of the long bones, and is a disease of early adult life. Its growth is relatively slow, and invariably accompanied with suffering; the skin is variously altered in 22 per cent., and the subcutaneous veins are prominent in 33 per cent. of all cases; the lymphatic glands are enlarged, and spontaneous fracture occurs in 11 per cent.; it does not pulsate, nor does it invade the joints; but the adjacent tissues are infected in nearly one-half of all cases. It is the most malignant of all the sarcomas, recurring in six-tenths of all cases after amputation, and invariably giving rise to metastatic deposits.

5. *Periosteal Round-celled Sarcoma.*—Periosseous round-celled tumors are developed around the shaft nearly twice as often as around the articular extremities of the bones. Like the preceding variety it is most common before the thirtieth year. Its increase is very rapid, and usually painful; the skin is adherent, discolored, or ulcerated in 51 per cent. of all instances; the veins are enlarged in 41 per cent.; the lymphatic glands are tumefied in 38 per cent.; spontaneous fracture occurs in 7 per cent.; and the temperature is elevated in 33 per cent. of all cases. The tumor never pulsates; but it invades the surrounding soft tissues in 50 per cent., and the joints in 15 per cent. of all examples. Local recurrence after operation is observed in one-half of all cases, and metastatic tumors are developed in two-thirds of all examples.

6. *Periosteal Osteoid Sarcoma.*—From the remarkable tendency evinced by the peripheral sarcomas, especially the spindle-celled variety, to undergo calcareous infiltration, or osseous transformation, a variety has arisen which is imperfectly understood, as it is generally described as osteoid cancer. In the most characteristic specimens of the disease the osseous or cretified material radiates from the surface of the affected bone to the circumference of the growth, in the form of long, delicate, fragile spicules, tufts, or plates, which are closely aggregated at their bases, and pursue a parallel course perpendicular to the surface of the bone, or diverge towards the circumference, as in fig. 405, from a sketch

sent me by the late Professor Buchanan, of Nashville. These tumors constitute 27 per cent. of all the sarcomas of the long bones, and 67 per cent. of the periosteal growths; and they develop, as a rule, around the epiphyses of the femur and the tibia. The average age of their appearance is twenty-two years. During their rapid growth the suffering becomes intense; the skin is altered in one instance out of every five; the veins are enlarged in less than one-third of all cases; the adjacent tissues are infected in 40 per

Fig. 405.
Osteoid Sarcoma of the Head of the Tibia.

cent. of all examples, but the joints are rarely invaded; and pulsation and spontaneous fracture are rarely observed. The lymphatic glands are swollen in 21 per cent. of all cases, and in one-half of these they are converted into bony tissue; secondary growths are met with in 65 per cent. of all cases; and the disease recurs locally after amputation in two-fifths of all examples. Hence, they are, next to the periosteal spindle-celled and round-celled, the most malignant of the sarcomas.

Treatment.—If left to itself, sarcoma inevitably proves fatal, whereas timely operations not only prolong life, but not infrequently eventuate in permanent recovery in all the varieties except the periosteal spindle-celled. In regard to the choice of the procedure, as to whether this should be amputation or excision, the decision must be given in favor of the former, the removal being effected as high up, or as near to the trunk as possible, for the reason that the joints are liable to be invaded by the disease, and that nodules of sarcomatous tissue may exist in the medullary canal at some distance above the original growth. In giant-celled tumors Dr. S. W. Gross has framed, in what I entirely concur with him, the following general rules for guidance in selecting the point at which amputation should be performed. For tumors of the lower epiphyses of the tibia and fibula, just below the knee; when the upper articular extremities of these bones are involved, through the lower part of the thigh; at the junction of the upper and middle thirds of the thigh for disease of the condyles; at the hip-joint for that of other portions of the femur; below the elbow for tumors of the lower epiphyses of the radius and ulna; through the lower third of the arm when the upper epiphysis of the ulna is affected; at the junction of the upper and middle thirds of the arm, for disease of the condyles of the humerus; and at the shoulder-joint when the head of the humerus is involved. When the growth is very bulky the incision may have to be made higher up. Thus, a sarcoma, as large as the head, commencing in the lower extremity of the radius, had best be removed by disarticulation at the elbow. In all of the other varieties of sarcoma, the rule should be to amputate as far as possible from the seat of the disease as may be consistent with the safety of the patient. Of nine cases of excision of the affected bone for giant-celled sarcoma, death ensued in four, either as the result of the operation or of recurrence of the disease, and moderately useful limbs were obtained in two. In deciding upon the propriety of an operation, enlargement of the lymphatic glands should not be regarded as a bar to interference, since their tumefaction was due to irritative hyperplasia in more than two-thirds of the cases in which their condition was determined.

2. OSTEOMA OR EXOSTOSIS.

An exostosis, of which fig. 406 affords a good idea, is an osseous outgrowth, the word, which is a Greek compound, signifying a bone growing from a bone. It is, in fact, a local

hypertrophy, a circumscribed tumor, possessing essentially the same structure as the bone from which it springs, and with the substance of which it is usually intimately identified.

The disease occurs chiefly in young and middle-aged subjects, being very infrequent before puberty, and after the fiftieth year. It is more common in males than in females, and is generally confined to particular bones, as those of the cranium and extremities, especially the femur, and the phalanx of the great toe. The superior maxillary sinus is

Fig. 406.

Exostosis of the Thigh-bone.

occasionally the seat of exostoses, as in a specimen in my collection, in which the inner surface of the left antrum is literally studded with these growths, none of which exceed a small grain of wheat, which they also much resemble in shape. A bony tumor in this locality sometimes acquires an enormous bulk, and, when both cavities are affected simultaneously, may occasion great deformity.

In the flat bones, as those of the head and pelvis, the outgrowth may occur upon either surface; in general, however, it evinces a preference for the external one, probably because it has a more perfect periosteum. When the tumor is attached to the inner surface, constituting what is known as an *enostosis*, its tendency is to encroach more or less seriously upon the contents of the cavity which the bone assists in forming. Enostosis is most common in the cranium of syphilitic subjects.

A tendency to exostosis is sometimes observed in several members of the same family, as in the case of a lady who was under my charge on account of a tumor of this kind on the shaft of the left radius, and whose sister and brother each had a similar enlargement, the former on the occipital bone, the latter on the clavicle. Boyer has recorded the particulars of a case in which the disease was hereditary, the patient's father, brothers, sisters, nephews, and children having all suffered in a similar manner.

The number of these outgrowths varies from one to a great many. Cases occur in which there is a kind of exostosic diathesis. Thus, in the Mütter collection there is the skeleton of a female in which nearly all the bones are thus affected.

Exostoses sometimes observe a symmetrical arrangement, tumors of the same size and shape occurring at the same points of the corresponding pieces of the two sides. Such a disposition is occasionally witnessed on the frontal bone and the lower jaw, but is most common on the humerus and femur, especially at their inferior extremities.

The volume of these growths is subject to no little diversity, some being very small, while others are extremely large—equal, perhaps, to the size of an adult head. The most bulky usually occur upon the bones of the extremities, particularly the lower part of the femur, although they are also occasionally seen upon the cranial, facial, and pelvic bones, where their presence may be a source of the most hideous deformity.

Their shape is also very variable; sometimes they have a distinct, well-defined outline, being of a globular, ovoidal, or hemispherical figure; occasionally they jut out like long, slender spines or stalactites; in another series of cases, they have a knobby, nodulated, tubercular, or mammillated appearance; and, lastly, instances occur in which they assume the form of plates or lamellæ. These varieties of shape are doubtless entirely due to accidental circumstances; but they nevertheless deserve attention, on account of their practical relations. In regard to their surface, this may be either perfectly smooth, scabrous, or spiculated; most generally the latter.

The adjoining sketch, fig. 407, represents a remarkable form of exostosis, from a drawing of a specimen kindly presented to me by Dr. Lewis, of Alexandria. It grew upon the right femur of a lady, fifty-one years old, having commenced when she was only nine years of age. The tumor, before removal, was about the volume of a cocoanut, oval, smooth, and very hard. The integument over its summit had latterly become inflamed and ulcerated, followed by a discharge of sanious matter, and the protrusion of a portion of bone. The general health becoming somewhat impaired, amputation was performed

Exostosis of the Femur.

at the lower third of the thigh, the woman making an excellent recovery. This case is additionally interesting from the circumstance that several of the relatives of the patient had been affected with similar tumors.

As to their origin, there is no doubt that, in the great majority of instances, exostoses arise without any assignable cause. On the other hand, they may often be traced directly to the effects of injury, as a blow or kick. In the distal phalanx of the great toe, a not uncommon seat of the disease, it is not unlikely that the pressure of the boot is able to produce it. Exostosis in the stump after amputation of the thigh and leg is probably due to the jarring which the femur and tibia experience during the operation of sawing, aggravated, perhaps, by a partial laceration of the periosteum. Numerous exostoses are sometimes developed under the influence of a syphilitic, gouty, or rheumatic state of the system.

The immediate cause of exostosis is formative inflammation, the process of development being precisely similar to that which governs the formation of normal bone. The concomitant inflammation is not always seated exclusively in the bone, but partly in the bone and partly in the periosteum; and cases occur in which there is reason to believe that the latter is mainly involved in the production of the tumor.

In regard to its structure, an exostosis differs in no wise from that of healthy bone. It is essentially composed of two parts, a compact and an areolar, the former inclosing the latter as a dense, firm layer, varying in thickness from the sixth of a line to a quarter of an inch, according to the volume of the tumor. The compact substance sometimes constitutes the greater bulk of the morbid mass, and there are cases, especially when it involves the cranium, where it is of the consistence of ivory, being so close and hard as to render it extremely difficult to saw it. Such a structure is represented in fig. 408, from a specimen in my collection. The areolar texture is sometimes directly continuous with that of the bone from which the exostosis grows; at other times, however, it is independent

Fig. 408.

Ivory-like Exostosis, showing its internal Structure.

of it, as in fig. 409, being either in immediate contact with the compact structure, or separated from it by a stratum of cartilage, or fibrous tissue. Its cells are of variable size and form, and are generally loaded with fatty matter, very much as in a short bone of the skeleton, or in the articular extremity of a long one.

The identity of the structure of exostosis with that of natural

Fig. 409.
Spongy Exostosis of the Femur, with a broad Base and pointed Processes.

bone is proved, moreover, by chemical analysis. Even when the new substance is of unusual firmness, as in the eburnized variety of exostosis, the difference is much less than might, at first sight, be imagined. The following comparative analysis of healthy bone and of an ivory exostosis, by Berzelius, places the subject in a clear light. The principal difference, it will be observed, consists in the presence, in the latter, of an unusual quantity of phosphate of lime, and in a marked diminution of carbonate of lime and salts.

	Healthy Bone.	Eburnized Exostosis.
Animal matter	33.30	28.57
Phosphate of lime and magnesium	54.20	68.88
Carbonate of lime and salts	12.50	2.00
Loss	00.00	00.55
	100.00	100.00

An enostosis is precisely of the same structure as an exostosis. The distinction, in fact, has reference merely to the situation of the tumor, the one, as the name implies, being developed upon the inner, and the other upon the outer, surface of the bone.

When an exostosis is seated in a part of the body which is habitually the subject of considerable motion, as, for example, the inferior portion of the femur, it is usually surrounded by a distinct capsule, a sort of synovial burse, designed evidently to ward off friction and facilitate gliding. The inner surface of the capsule, which is of variable thickness, is perfectly smooth, unadherent, and lubricated by a sero-oleaginous fluid, so as to qualify it the better for the performance of its functions. Where no motion is required, the growth lies in immediate contact with the natural structures, the union between them being commonly so intimate as to demand a careful use of the knife to effect their separation. Occasionally, indeed, the soft parts are partially imprisoned in the osseous tumor, thereby rendering the dissection peculiarly tedious and difficult.

The progress of this disease is generally tardy; it is only now and then that a case pursues a different course, or where the symptoms partake of an acute character. A syphilitic exostosis occasionally attains a considerable bulk in a short time, and a similar occurrence has been observed, although less frequently, in the rheumatic form of the complaint. Under such circumstances, the formation of the tumor is generally attended with severe pain, liable to nocturnal exacerbations, tenderness and swelling of the part, and more or less constitutional disturbance. Ordinarily, however, there is nothing of the kind; the disease comes on slowly and almost imperceptibly, the first thing that arrests attention being a small tumor, which is altogether insensible, and exceedingly tardy in its progress, years elapsing before it acquires the size, perhaps, of a pullet's egg. If it be superficial, so as to admit of examination, it will be found to be hard and immovable from the first, and so it generally continues ever afterwards, whatever may be its bulk. Meanwhile, although it may itself be entirely indolent, it may be productive of pain in the surrounding structures, by the compression which it exerts upon the nerves, and in this way the suffering is sometimes rendered exceedingly severe, being often of a neuralgic character, darting about in different directions, and extending far beyond the seat of the bony growth. When the tumor is situated among parts that are much exposed to motion, it frets and irritates them, and thus greatly aggravates the local distress. As the morbid mass enlarges, it must necessarily act obstructingly, interfering with the functions of the affected structures, and ultimately, perhaps, entirely abolishing them. Thus an exostosis of the orbit may continue to increase until it pushes the eye completely out of its socket, not only filling the whole cavity, but encroaching more or less extensively upon the cheek and cranium. In a similar manner an osseous tumor may project into the pelvis, and impede the delivery of the child. Boyer refers to a case in which a growth of this kind, attached to the pubic bone, pressed against the neck of the bladder, and caused retention of urine, for the relief of which it was impossible to introduce the catheter. An exostosis of a rib may compress the lungs; of a vertebra, the spinal cord; of the cranium, the brain. Another effect is that it stretches, flattens, and displaces the muscles, tendons, nerves, and vessels, thereby partially disqualifying them for the exercise of their functions. Sir Astley Cooper has recorded an instance of gangrene of the arm from compression of the axillary artery by an exostosis of the lower cervical vertebræ.

Sometimes the coverings of the tumor are invaded by ulceration and even gangrene, thereby more or less freely exposing its surface, which occasionally, in turn, takes on the same kind of action. At other times the morbid mass perishes, apparently from a want of nourishment, and is detached very much in the same manner as a slough of the soft parts. Exostoses of immense volume occasionally experience such a fate. The occurrence is most likely to happen when the tumor has a narrow, cartilaginous base.

The *diagnosis* of exostosis cannot always be easily determined unless the tumor is situated superficially, when its great firmness and immobility generally serve to point out its true character. When the tumor occupies some internal cavity its nature may be suspected, but no surgeon, however skilled in diagnosis, can positively say to what class

of growths it belongs. On the other hand, an exostosis may sometimes seriously interfere with the diagnosis of other affections. Thus, a tumor of this kind, occupying the pelvic cavity, may impinge against the bladder, or even project into it, in such a manner as that the sound, coming in contact with its surface, shall impart a noise and sensation similar to those communicated by the presence of a calculus.

An exostosis, lying immediately beneath an artery, may simulate an aneurism, as in a case mentioned by Stanley. A patient was admitted into the Middlesex Hospital with a tumor presenting all the symptoms of aneurism of the subclavian artery. The pulsation in front of the swelling was very strong, and extended over a large space; but none could be detected at the sides. The axillary artery beat feebly, and no motion whatever existed in the vessels of the arm. A careful examination discovered an exostosis of the first rib, pushing the subclavian artery forwards, and flattening it.

The *prognosis* varies. So long as the tumor is small and indolent, it may commonly be considered as of little moment; but when it increases rapidly, or is so situated as to interfere with the functions of a joint, or to encroach upon an important organ, it becomes a matter of serious import; the more so, because it is then not always possible to get rid of it by an operation, and there is generally nothing else that can reach it. When an exostosis projects into a joint, an operation is a hazardous undertaking, liable to be followed by the worst results; and when it occupies an internal cavity it is generally utterly inaccessible. An exostosis of the inner surface of the cranium usually proves dangerous by determining epilepsy, paralysis, and other bad symptoms; in the pelvis it may, as already stated, interfere with parturition, and in almost any part of the body it may induce neuralgia.

Treatment.—The treatment of exostosis must be guided, in great degree, at least in its earlier stages, by the nature of the exciting cause. When the affection has been occasioned by a deranged state of the system, or by the rheumatic, gouty, or syphilitic poison, colchicum, aconite, and iodide of potassium, either alone, or in union with bichloride of mercury, will be indicated, and can hardly fail, if judiciously administered, to prove highly beneficial. Under the influence of these remedies growth is often promptly arrested, and the tumor eventually entirely dispersed. The use of mercury is particularly serviceable in these cases, but to produce its full effects it is generally necessary to carry it to the extent of gentle ptyalism, maintained for some time, especially in obstinate cases. When the complaint gives rise to much pain, opium, conjoined with diaphoretics, will be required.

Topical applications are particularly useful when the tumor is of rapid growth, exquisitely sensitive, and the result of external injury, or of a syphilitic taint of the system. In the earlier stages of the disease, the remedies most to be relied upon are leeches, blisters, saturnine lotions, and tincture of iodine employed in the ordinary way. If blisters, which are the most valuable of all topical means, are used, the skin over the tumor should be raised very thoroughly, a free discharge being afterwards maintained by some stimulating unguent, with a view to a permanent pyogenic effect. In the syphilitic form of exostosis, mercurial fumigations sometimes answer a good purpose, succeeding when all other remedies fail.

When the tumor has attained considerable bulk, and, above all, when it is of long standing, and of great firmness, or productive of excessive suffering, the only chance of relief is ablation; or, if this be impracticable on account of the nature and extent of the exostosis, amputation of the affected limb. The incisions through the integument are made as in ordinary growths, the most eligible shape being the crucial, elliptical, curvilinear, or T-like. Free exposure is effected, without interfering with any important structures, the division of which might afterwards impair the usefulness of the parts. If the skin is diseased, or much attenuated, the affected portion is, of course, removed. The exostosis is then attacked with the knife and a metacarpal saw, the former alone, if stout, being commonly sufficient to effect ablation when the tumor has a cartilaginous base, or an unusually soft structure. In general, however, the saw will be necessary, and there are many cases where the gouge, chisel, and trephine may advantageously be employed. If the tumor has a very large base, and is insensibly blended with the substance of the bone from which it grows, it should be divided into several sections, by perforating it at different points, and then detaching them separately, or piecemeal. Various kinds of saws have been invented for removing exostoses, but they are all more or less complicated and unwieldy, and may well be replaced by the more simple instruments in common use. The surgical engine has lately been called to the surgeon's aid in the removal of exostoses, and promises to supersede most, if not all, other instruments hitherto used in these ope-

rations. In whatever manner the ablation is effected, the bony portion of the wound should be rendered as smooth as possible by means of the raspatory, otherwise it will seriously interfere with cicatrization. As it is, there will, in any event, be more or less suppuration, retarding the progress of the cure, and the patient may congratulate himself if he escapes erysipelas and other bad consequences. The hemorrhage attending the operation is usually very slight. The edges of the wound should be lightly approximated, and the parts kept constantly wet with saturnine and anodyne lotions, either cold, cool, or tepid, according to the exigencies of the case.

3. CHONDROMA.

The cartilaginous tumor may be developed in the cancellated structure or upon the outer surface of the bones, beneath the periosteum, the latter mode of origin being the more common. Its figure is globular; its surface rough, or nodulated; its consistence firm, dense, and elastic; its color white, or grayish. The morbid mass may attain a large bulk. When it originates in the central part of the bone its capsule persists longer than in other central osseous tumors; but it finally becomes attenuated and gives way at one or more points, and thus allows the morbid growth to protrude beneath the surrounding soft tissues.

This tumor ordinarily affects only one bone, is not, as a rule, malignant, and is productive of little inconvenience, except from its size and weight. It is peculiar to early life, is often directly chargeable to external violence, manifests, when of long standing, a tendency to undergo certain degenerations, especially the calcareous, mucous, and cystic, is generally slow in its progress, and occasionally appears simultaneously in several parts of the skeleton. Every portion of the osseous system is liable to it; but the pieces most frequently affected are the metacarpal bones, the phalanges of the fingers, the humerus, and the lower jaw. In old cases the growth sometimes undergoes partial ossification, as in the specimen represented in fig. 411. Fig. 412 exhibits a cartilaginous tumor of the ribs, from a drawing of a preparation in my collection.

Although the periosteal and central chondromas of the long bones possess many features in common, they exhibit certain contrasts, which have been carefully studied by Dr. S. W. Gross, and which may prove useful in distinguishing them from each other, and from the sarcomatous growths. Thus, the periosteal tumors appear between the tenth and sixty-first years, or, on an average, at the age of twenty-six; nearly two-thirds of all cases are met with in females; pain is present throughout in 47 per cent.; the subcutaneous veins are dilated in 21 per cent.; the skin is variously altered in one example in every ten; spontaneous fracture, or fracture from slight causes, is met with in 5 per cent.; metastatic deposits occur in 3.17 per cent.; and the lymphatic glands are never enlarged. The central tumors, on the other hand, appear between the seventeenth and fifty-ninth years, the average being

Fig. 410.

Cartilaginous Tumors of the Hand.

the thirty-third year; four-fifths of all cases are met with in males; pain is experienced throughout in 30 per cent.; the superficial veins are enlarged in 60 per cent.; the skin is variously altered in one example in every five; fracture is met with in 20 per cent.; metastatic tumors are unknown; and the lymphatic glands are enlarged in one instance in every ten.

A tumor of this kind occasionally attains an enormous bulk, as in a chondroma of the scapula and humerus in a young man of twenty-six, whom I saw at the College Clinic, the weight of the mass being upwards of thirty pounds.

There is a form of this tumor to which, from the superaddition of sarcomatous tissue, the term sarco-chondroma is applied, a striking example of which came under my observation, in 1871, in a strong, robust man, thirty years of age, in connection with the tenth rib, which it involved from its angle almost to its costal attachments. Extending from near the spinal column obliquely downwards and forwards to within an inch of the crest of the ilium in front, it was seven years in attaining its growth, one-half being added during the last twelve months. It was of a flattened, ovoidal shape, with the narrow end below, perfectly painless, very firm, and unadherent to the skin. Excision was effected without any material loss of blood, but during the dissection a portion of pleura, very much thickened, and about the size of the palm of the hand, was unavoidably ex-

posed, although not penetrated, separation being accomplished by enucleation. Death occurred on the twelfth day from pleuro-pneumonia.

The tumor, after removal, was found to weigh two pounds and a half, its greatest longitudinal circumference being twenty inches, and the transverse twelve. It was distinctly lobulated, and was, apparently, composed of two portions; an upper, cartilaginous, finely tuberculated, bright, grayish-white, corresponding with the affected rib; and a lower, of

Fig. 411.

Fig. 412.

Chondromatous Tumor undergoing Ossification.
Chondromatous Tumor of the Ribs. *a.* External Appearance. *b.* Internal Structure.

a dense, shining, fibrous appearance, succulent, of a pale straw color, consisting of cartilage cells, most of which were filled with drops of oil, and of an intercellular substance, made up, in great degree, of fasciculated spindle-celled tissue. The more rapidly developed portions of the morbid mass were interspersed with large spindle-cells, mottled with vascular and greenish gelatinous points, and inlaid with cysts of varying sizes, some of which were filled with mucous fluid, while others were undergoing disintegration. There were also, in different situations, islets of hyaline cartilage, calcareous deposits, and delicate masses of bone, with well-marked lacunal cells but no Haversian canals, the whole growth affording a remarkable illustration of the various degenerations which such a tumor occasionally experiences during the progress of its development.

The only remedy for these tumors is free excision or amputation, as when they occupy an extremity. All local and general means, even in their earlier stages, are unavailing.

4. OSTEOID CHONDROMA.

The term osteoid chondroma has been applied by Virchow to those peripheral neoplasms which originate in the ossifying cell-layer existing between the periosteum and the surface of growing bones, and is called by him membranous or osteoid cartilage, since it forms the starting point of ossific processes, as indicated by the normal growth of bone and the development of callus, osteophytes, and other pathological formations, and, for that reason, is the equivalent of cartilage. Holding an intermediate position between osteoma and chondroma, osteoid chondroma is made up of cells, which differ from those of cartilage in being small, fusiform, or round-oval with short prolongations, and devoid of capsules. They lie free in a very dense, striated, but non-fibrillated, sclerosed, or cartilaginous intercellular substance, which is greatly in excess of the cellular elements, although the latter may predominate, and increase in size, in which event the tumor becomes sarcomatous. On section the mass is seen to be extensively pervaded by bone, at one point fragile and porous, at another dense and hard, which forms a delicate skeleton or framework, attached to the surface of the bone. In some specimens the ossific process has advanced so far as only to require the deposition of the salts of lime in the remaining softer portions

of the growth to convert it into an osteoma. It is rich in bloodvessels which penetrate its very substance, in which respect it differs from chondroma.

Osteoid chondroma is seated most frequently on the articular extremities of the shafts of the long bones, and on the lower jaw. Some pathologists, indeed, are disposed to include it among the ossifying periosteal sarcomas, from which they are unable to distinguish it, either by its minute, gross, or clinical features.

Osteoid chondroma does not possess a single element by which it may be diagnosticated from periosteal sarcoma. It is most frequent in young persons; is of a firm consistence, and of an ovoidal or pyriform shape, with a smooth or only slightly uneven surface; grows rapidly, and attains a large volume. Closely connected with the bone, it receives an investment from the periosteum, which, however, may finally give way, and permit the mass to infiltrate the surrounding tissues. The huge dimensions which it may acquire are well illustrated by a case under the charge of Sir Astley Cooper, in a girl, thirteen years of age, in whom the tumor, of twelve months' growth, and occupying the inferior maxilla, measured sixteen inches in circumference. The tongue was pushed not only to one side but backwards into the pharynx, while the epiglottis was recurvated upon the superior aperture of the larynx, death finally ensuing from the combined effects of starvation and respiratory embarrassment. The prognosis is bad, as the tumor is not only liable to recur after removal, but to give rise to metastatic deposits. The only remedy is amputation as far as possible from the seat of the disease, when an extremity is involved, or excision when the lower jaw is affected.

5. FIBROMA.

Fibrous tumors of bones, whether originating in the periosteum or in the endosteum, resemble similar formations in other tissues. As hyperplastic outgrowths of the periosteum, they are met with most frequently in connection with the base of the skull, as polyps, in the antrum of Highmore, and upon the alveolar borders of the upper and lower jaws, where they give rise to one form of epulis. In any of these situations they may attain an enormous size, and commit frightful ravages by their encroachment upon the surrounding structures.

The central or endosteal variety of fibroma is confined almost exclusively to the lower jaw, although it has also been observed in the extremities of the long bones and in the phalanges of the fingers. In the former situation the plates of the maxilla are expanded so as to form a round, or oval, and more or less distinctly lobulated tumor, the interior of which is now and then intersected by osseous spicules.

The treatment of these affections must vary according to their site, complete removal being indispensable under all circumstances, by detachment with suitable instruments or by excision of the entire thickness of the bone, as when they occupy the jaw.

6. MYXOMA.

Pure myxoma of the osseous tissue is very uncommon, the majority of the recorded instances of this affection being due to mucous degeneration of chondromas. A case in which a myxomatous tumor grew from the body of the sphenoid bone, outside of the dura mater, fig. 413, came under my notice in a patient who died at the age of thirty-nine years from epilepsy, produced by a fall twelve months previously. On examination, Dr. Colescott and myself found a lobulated tumor, of irregular form, and about the size of a pullet's egg, which had flattened the Varolian bridge, and had evidently induced the disease in question. It is generally developed from the medullary membrane of the lower jaw, disparting the compact tissue, which it expands into a thin, bony investment, as in other central osseous growths. Its progress is slow, but, as it increases, the bony capsule is finally perforated. It is a strictly local affection, evincing no disposition to return after removal, or to contaminate the neighboring lymphatic glands.

Fig. 413.

Myxomatous Tumor.

7. ANGIOMA.

The only form of vascular tumor met with in the bones is aneurism by anastomosis, to which attention was first clearly drawn by Mr. Stanley. The disease, which exhibits the same general characters as an arterial erectile tumor of the soft parts, and which is represented in fig. 414, has been chiefly noticed in the broad bones, especially those of the cranium of young children. The causes of this lesion are obscure. Any external injury, by disturbing the vascular action of the bone, might produce it.

Fig. 414.

Anastomotic Aneurism of Bone.

The enlargement, even in its early stages, is tense, painful, and attended with distension of the superficial veins, swelling of the surrounding structures, and slight discoloration of the skin. In a short time a deep-seated pulsation or throbbing synchronous with that of the left ventricle, and similar to what is witnessed in some erectile tumors, may be perceived in the affected part. In the advanced stage of the malady the beating is accompanied by a sort of undulating movement, and is easily interrupted by compressing the carotid artery.

When anastomotic aneurism involves the scapula, the lower jaw, or the clavicle, and it is of limited extent, it may be removed. When it is situated in the cranial bones, it gradually destroys the osseous tissue, and ultimately involves the brain and its envelops, rendering interference out of the question. Several cases have been reported in which the carotid arteries were tied for this disease, but in none with any permanent benefit.

8. HYDATID TUMORS.

The bones are occasionally the seat of hydatids, but the occurrence is very uncommon. The first account of these bodies in these situations was given by two Dutch pathologists, Van Vy and Van der Haar, whose observations have since been confirmed by other observers, as Keate, Cruveilhier, and Lucas.

Although it is extremely probable that all the different classes of bones are liable to these formations, they have hitherto been observed almost exclusively in the long and flat bones, particularly in the tibia, for which they appear to have a decided preference. They have been found seven times in the tibia, five times in the humerus, five times in the bones of the pelvis, four times in the bones of the skull, three times in the vertebræ, twice in the femur, and once in the phalanx of the finger. What was formerly known under the vague name of spina ventosa was an osseous tumor which probably occasionally contained bodies of this kind.

These bodies always take their rise from germs contained in the blood developed in the spongy texture of the bones, as this alone affords them an opportunity of growing and expanding, the compact tissue being too dense and firm to admit of their increase. The only exception to this occurs when they form in the frontal sinus, but even here there is no new law in operation, since the cavity in question is, in fact, only a large cell, well adapted as a residence for such bodies. Of the exciting or predisposing causes of these bodies nothing whatever is known; for if, as has occasionally happened, they have formed in a particular portion of the skeleton after the occurrence of a blow, contusion, or other injury, it does not prove that their development was the consequence of such mischief.

Hydatids occur with nearly equal frequency in both sexes; and all the patients in whom they have hitherto been found were adults, excepting four, of whom two were children three and seven years of age. Borchard has recorded a case in which they existed in several situations in the same individual.

Examination has proved that these bodies are veritable acephalocysts, similar to those which occasionally infest the liver, ovaries, lungs, and other internal viscera. Of a spherical or rounded shape, they are sometimes irregularly flattened or compressed,

especially the older ones, and they vary in size from a pea to that of a marble, their dimensions being evidently influenced by their age, and the extent of the cavity in which they are developed. Their number, which is seldom large, is usually in an inverse ratio to their volume. They are inclosed in a sort of parent cyst, soft in structure, thin, and of a whitish appearance, and they float about in the midst of a serous fluid, of a saline taste, and partially coagulable by heat and acids; circumstances clearly betraying its albuminous character.

The cavity in which these bodies are situated is, evidently, in the first instance, simply a cell of the areolar tissue, in which the germ of the parasite is deposited, and in which it is destined afterwards to attain its full development. As its growth proceeds, it presses upon the osseous matter, pushing its fibres farther and farther part, at the same time causing a partial removal of it by the action of the absorbents, until what remains is at length converted into a mere bony sheet, hardly as thick as a piece of parchment, elastic, and crackling under the finger. The shell is lined, as already stated, by a thin, closely adherent membrane, which evidently plays an important part in the development and protection of the new being. Cases occur in which it consists of several compartments, although in general it is unilocular. The bone immediately adjacent to the disease is usually thickened and roughened by irregular deposits.

The *symptoms* attending the formation of these bodies are extremely obscure, and cannot, for a long time, be separated from those which accompany other diseases in and about the skeleton. Their growth is always very tardy, and a number of months generally elapse before there is any pain or discoloration of the surface. The patient is merely aware that there is some tumor, steadily augmenting in bulk, and slowly encroaching upon the surrounding parts; hard and firm at first, afterwards more soft, and ultimately becoming distinctly elastic, and emitting a peculiar crackling sound on pressure very similar to that of dry parchment. When deep-seated, it causes a gradual wasting of the superimposed tissues, the muscles and tendons being spread out in the form of thin ribbons, while portions of the fibrous membranes are actually absorbed. Meanwhile the tumor mechanically impedes the functions of the surrounding parts, pain and tenderness set in, and the skin evinces signs of irritation. At this stage of the complaint the affected bone sometimes gives way under the most trivial accident, refusing afterwards to unite, or undergoing consolidation only after a long while. Occasionally the most prominent portion of the tumor ulcerates, and discharges a part of its contents. The health remains good for years, but in the end it is always much impaired by the local distress.

The most important diagnostic signs of this affection are, the tardy progress of the tumor, the absence of pain and swelling, the change from a hard, incompressible substance to one of comparative softness and even elasticity, and the complete absence of all appearance, both local and constitutional, of malignancy. After all, however, these symptoms are merely of a negative character; for at last the only reliable source of information is the exploring needle, although this also, unfortunately, is not available until the morbid growth has acquired great bulk, and is almost on the verge of bursting. Even the elastic feel and crackling noise which, in the latter stages of the complaint, form such prominent features, are of no diagnostic avail, as they are common to several other varieties of bony tumors, especially the cystic, properly so called.

Hydatid disease of the osseous tissue is always a grave occurrence, not so much on account of the damage to the general health as of the injury it inflicts upon the affected bone, weakening its structure and thus impairing its usefulness, generally to an irremediable extent. In some of the recorded cases the acephalocysts burst into the knee-joint, causing destructive inflammation, while in others the animals perished, and gave rise to high constitutional disturbances, attended with excessive pain and hectic fever.

The *treatment* of this disease is by extirpation, performed early, before there is any serious structural lesion of the bone. The tumor being freely exposed by an incision, either crucial or elliptical, and attacked with the saw, pliers, trephine, or chisel and mallet, as may seem most advisable. Its contents being turned out, the lining membrane of the osseous shell is carefully peeled off, or, if this be impracticable, painted with a strong solution of iodine, to destroy its secreting surface, lest there be a speedy reproduction, if not of hydatids, at all events of serous fluid. The cavity is then filled with oiled lint, and the flaps, being approximated, are lightly held in place with a few strips of adhesive plaster. The cavity gradually shrinks, and a cure is ultimately effected by the granulating process.

When the case is a very aggravated one, involving the entire circumference of the

affected bone, or when the hydatids open into a joint, the only resource is resection or amputation, the former being applicable only when the disease is of limited extent, while amputation is absolutely necessary when it has induced so much disturbance, local and constitutional, as to threaten life.

<div align="center">SECT. XVII.—TUBERCLE.</div>

Tubercles of the osseous tissue are much more common than is generally imagined. The bones usually affected are the vertebræ, the short bones of the hand and foot, and the articulating extremities of the long bones. The particular seat of tubercles is the spongy texture, from the marrow of which they arise, although occasionally they are formed upon the outer surface of the bones, beneath the periosteum.

There are two varieties of form in which this matter is deposited. In one, perhaps the more common, the tubercles are encysted, the inclosing membrane, which varies in thickness from the fifth of a line to half a line, being composed of plastic matter, very soft at first, but gradually becoming harder and harder, until finally, in some cases, it acquires the character of fibro-cartilage. It is of a dull, grayish color, is made up of delicate, inelastic fibres, and is frequently furnished with small vessels, passing into it from the surrounding structures. The number of tubercles is generally small; their size ranges from a pea to that of a cherry; and they are of a yellowish, opaque appearance. When they become softened, as they commonly do in a few months, the pus either works its way out, or it escapes, by a kind of fistulous route, into a neighboring joint, establishing thereby an analogy with pulmonary tubercles opening into the bronchial tubes. Sometimes a spontaneous cure takes place, the tubercle granules being absorbed, and the cavity occupied by the cyst being obliterated by osseous matter.

In the second variety, the tubercular matter is deposited directly into the cells of the osseous tissue, forming grayish, semitransparent, opaline patches, from the one-sixth of an

Fig. 415.

Bone infiltrated with Tubercle.

inch to an inch in diameter. This infiltration, exhibited in fig. 415, is noticed chiefly in the bodies of the vertebræ and in the bones of the tarsus. The bony tissue immediately around is sometimes deeply injected, and the trabeculæ are eroded. In this, as in the preceding variety, the tubercular deposit, after having existed for some time, gradually softens, and the cells in which it was contained are filled with earthy matter. This, however, is not always the case; for now and then the ulcerative process continues until the bone is totally destroyed.

The progress of tubercular disease of the bones is always chronic, although not equally so in both forms, the infiltrated proceeding more tardily than the encysted, and causing generally also a greater amount of havoc in the osseous tissue. There is nothing definite, however, in regard either to the commencement of the softening process, or to the ultimate elimination of the resulting matter from the affected structures. Much will doubtless depend, in every case, upon the condition of the system, the age of the patient, and the presence or absence of complications. As a general rule, from six to twelve months will elapse from the moment of the deposition of the tubercular substance to the completion of the softening process. The pus left by the disintegration of the deposit is similar to that which occurs in the lungs in the advanced stage of phthisis, being of a pale yellowish color, bordering slightly upon greenish, and of a thin, fluid consistence, with small whitish flakes not unlike soft-boiled grains of rice. After an opening has been effected into the abscess, the discharge generally becomes very watery and bloody, as well as irritating, and comes away in large quantities, a number of sinuses often existing in the diseased parts, as if they were necessary to carry off the superabundant secretions. In many cases, broken-down osseous tissue is intermingled with the pus, passing off either as little granules or as minute fragments, which not unfrequently choke up the abnormal track, and thus excite new irritation.

The adjoining cut, fig. 416, from a specimen in my cabinet, exhibits the effects which a tubercular abscess may exert upon the osseous tissue, in causing a well-marked excavation, similar to what occurs in the lungs.

Fig. 416.

The abscess that arises from the disintegration of tubercular matter is the form which is usually met with in bone, the phlegmonous, as stated elsewhere, being of extremely rare occurrence. The symptoms attending it are generally obscure, but its existence may be suspected when, along with the ordinary signs of osteitis, the affected part is the seat of circumscribed, deep-seated, gnawing pain,
Tubercular Excavation of the Cuneiform Bone.

with excessive tenderness at one particular spot, and a glossy, shining, œdematous condition of the integument. The breaking of the abscess is always preceded by considerable swelling of the soft structures, and by more or less disturbance of the system, the constitution frequently sympathizing severely with the local trouble. In addition to these circumstances, the history of the case, as the age of the patient, the site of the morbid action, and the absence of coexistence of strumous disease in other structures, will generally furnish useful light, and thus materially aid in the establishment of a correct diagnosis.

The *treatment* of tuberculosis of bone does not materially differ from that of tuberculosis generally. As the local deposit is usually merely a reflection of the state of the system, the great object should be to employ such remedies as are necessary to modify this condition of the constitution and to provide for the supply of a better and richer blood. The principal means included under this head are, a well-regulated and adequately nutritious diet, cod-liver oil, and the various chalybeate preparations, either alone, or in union with quinine, mild purgatives, and gentle exercise in the open air.

The local remedies are of the ordinary antiphlogistic character, consisting of leeches, blisters, and tincture of iodine, with early and free incisions of the soft structures to relieve pain and tension. If the existence of an abscess is suspected, the trephine must promptly be employed, the operation and after-treatment being conducted in the same manner as in acute abscess of bone.

SECT. XVIII.—NEURALGIA.

Neuralgia of the osseous tissue is infrequent. I have seen vast numbers of cases of neuralgia of the soft structures in almost every part of the body, but comparatively few of neuralgia of the bones. In nearly every instance that has fallen under my observation the disease was associated with some organic lesion of the affected texture, such as abscess, caries, exostosis, or interstitial deposits into the Haversian canals and cancellated tissue, thereby compressing the vessels and the nerves distributed through their tunics. A lady, aged fifty, had long been afflicted with neuralgia of the cranium, caused by the falling of a window-sash upon the upper and posterior angle of the left parietal bone. The pain, without observing any regularity in its accession, gradually increased in severity, and became at length so intense as to require from one to two drachms of morphia a week, besides enormous quantities of sulphuric ether, even for temporary relief. The seat of pain was a small spot, not larger than the end of a finger, and exquisitely tender to the touch. A disk of bone, embracing the affected portion, being removed with the trephine, an exostosis, not more than the eighth of an inch in thickness, was discovered upon its inner surface, which thus at once explained the nature of the case. Complete recovery followed the operation.

A married woman, aged twenty-eight, had suffered, at times, most acute and distressing pain from a small bony tumor at the anterior and outer part of the lower extremity of the left radius. The tumor had come on about twelve years previously, and had all along been exquisitely sensitive on pressure even on the slightest touch. It projected but little beyond the natural level, and was unaccompanied by any visible change in the soft parts. The pain had been liable to periodical exacerbations, and was often so severe as to deprive the woman of appetite and sleep. The general health had always been good; the complexion denoted a robust state of the system, and the menstrual function was

usually performed with great regularity. Upon removing the tumor, I found that its substance was almost as hard and dense as ivory. The pain at once disappeared, and has never returned.

I have met with a number of cases similar to the last, which may be regarded as, in some degree, typical of this affection as it usually appears in the bones. Most of them occurred in young females, between the ages of fifteen and thirty, without, seemingly, any direct connection with the catamenial function, or any marked hysterical predisposition. In all these cases, the pain was liable to periodical exacerbations, not, however, by any means, always coincident with menstruation, and the parts were exquisitely sensitive under motion and pressure. The pieces that are most commonly affected are the radius, ulna, tibia, fibula, and clavicle, along with the skull and the innominate bones. The coccyx also not unfrequently suffers, especially in married women who have borne children.

Neuralgia of bone may arise spontaneously, or be a result of direct injury, as a blow, wound, or contusion, causing inflammation in the affected part. It may also be produced by a syphilitic taint of the system, as is witnessed in the tertiary form of this disease, in which the pains are not unfrequently of a darting, shooting, lancinating nature, or else dull, heavy, and aching, as in neuralgia of the soft structures. In abscess of bone the suffering is frequently of the same character; hence the difficulty so often experienced in discriminating between the two affections. The disease is frequently associated with neuralgia in other parts of the body.

What the precise nature of the change is which the osseous tissue undergoes in this affection has not been determined. The probability is that it is sometimes altogether functional, while at other times it depends upon interstitial deposits, either as a simple hypertrophy or as a small exostosis, compressing the vessels and nerves at the seat of the disease, and thus causing the excessive pain which so often attends it.

The *treatment* of neuralgia of bone is too often conducted upon empirical principles; a circumstance, doubtless, due to the fact that it is generally difficult, if not impossible, to ascertain the true nature of the disease. In recent cases, especially in such as are directly chargeable to the effects of external injury, a free incision down to the seat of the disease, dividing the periosteum and even the superficial layer of the bone, will occasionally effect a prompt cure, especially if the wound be kept open for some time with stimulating dressings to promote discharge. Now and then a small issue, made with the actual cautery, answers an excellent purpose. When the cause is of a syphilitic nature, iodide of potassium and mercury are the best means of relief. Quinine, arsenic, and strychnia are indicated when the disease is of miasmatic origin. In obstinate cases, the only reliable plan is removal of the affected bone with the trephine or other suitable instrument, as the object is to get rid of the compressing agent, whether this is merely simple hypertrophy of the part, or an exostosis, properly so termed. The late Dr. Nott, of New York, twice excised the greater portion of the coccyx for the cure of this disease, and a similar operation has been performed by others, although not always with a satisfactory result.

SECT. XIX.—FRACTURES.

1. GENERAL CONSIDERATIONS.

There is no class of injuries which a practitioner approaches with more doubt and misgiving than fractures, or one which demands a greater amount of ready knowledge, self-reliance, and consummate skill. Constant in their occurrence, and often extremely difficult of diagnosis and management, they frequently involve consequences hardly less serious and disastrous to the surgeon than to the patient himself. If I were called upon to testify what branch of surgery I regarded as the most trying and difficult to practise successfully and creditably, I should unhesitatingly assert that it was that which relates to the present subject, and I am quite sure that every enlightened practitioner would concur with me in the justice of this opinion. I certainly know none which requires a more thorough knowledge of topographical anatomy, a nicer sense of discrimination, a calmer judgment, a more enlarged experience, or a greater share of vigilance and attention; in a word, none which demands a higher combination of surgical tact and power. As for myself, I never treat a case of fracture, however simple, without a feeling of the deepest anxiety in regard to its ultimate issue; without a sense of discomfort, so long as I am conscious that, despite the most assiduous attention and the best directed efforts, the patient

is likely to be lame and deformed for life. A crooked limb, whether rendered so by injudicious treatment or not, is an unpleasant sight to a sensitive surgeon, inasmuch as it continually reminds him of his bad luck or want of success. I do not wish by these remarks to be understood to say that it is always in his power to cure these accidents without deformity or impairment of function. Such a view would be contrary to experience and common sense. There are many cases of fracture which do not admit of any other result, however attentively or skilfully they may be treated ; and there are not a few which turn out badly, disgracefully badly, simply because of the want of proper coöperation of the patient. In such cases no surgeon is responsible.

A fracture is a solution of continuity of the osseous tissue, or, in other words, a division of the bony fibres, occasioned by external violence or muscular contraction. The lesion presents itself in various forms, of which the principal are the simple, compound, comminuted, impacted, and complicated. To these may be added the incomplete fracture, in which a bone, instead of being entirely broken, is divided only in a portion of its diameter.

A fracture is said to be simple when there is no wound of the soft parts directly over the ends of the fragments, so as to expose them to view, or permit them to be felt. It is, in fact, a subcutaneous wound of a bone, and nothing more. The case is a simple one, so far as the bone is concerned, even if there be a wound in the immediate vicinity of the fracture, provided it has no direct communication with it. A fracture is compound when there is an opening in the skin and muscles extending down to the bone, the ends of which often protrude through the wound, girted, perhaps, by its edges. When a bone is broken into a number of pieces, the term comminuted is applied to it. The word impacted is employed to signify that the extremity of one fragment is forced into that of the other. Finally, fracture is complicated when it is associated with a dislocation, a wound, hemorrhage, laceration, or other mischief. It will greatly facilitate the study of the subject if all these terms, excepting the first and last, be discarded. Hence, after some general observations, I shall treat first of simple fractures, and afterwards of fractures complicated with other lesions.

All the bones of the body are liable to be broken, although not by any means with equal frequency. Those which are most prone to suffer in this manner are the long bones of the extremities, particularly those of the leg and forearm. The clavicle is also often fractured. The scapula, the two jaw-bones, the sternum, ribs, innominate bones, vertebræ, sacrum, and coccyx, together with the bones of the hand and foot, are rarely broken, owing either to their protected situation, to their mobility, or to the manner in which they are united to each other and to the surrounding parts. It may be stated also, as a general law, that the long bones are more liable to give way at or near their middle than at their extremities ; a circumstance of some importance in a diagnostic and practical point of view.

The relative frequency of fractures of the bones of the superior and inferior extremities varies in different institutions and in different localities, according to the nature of the occupations of those who are the subjects of them. The following table, composed of the statistics of four different hospitals, shows the preponderance to be very slightly in favor of the lower limbs :—

	Cases.	Upper extremity.	Lower extremity.
Pennsylvania Hospital	7670	3760	3910
Hôtel-Dieu, Paris	1856	850	1006
Middlesex Hospital, London	1280	764	516
Naval Hospital, Calcutta	1346	665	681
	12,152	6039	6113

Respecting their direction, fractures may be oblique, transverse, or longitudinal. Of these varieties, the first is by far the most common, although it is impossible, from the want of statistics, to estimate its relative frequency. My experience is that transverse fractures, except in young children, are extremely rare, and even in them they are by no means frequent. In the extensive osseous collection of Dr. Mütter, now in the College of Physicians, there is not a solitary specimen of the kind ; and my own is equally barren. These remarks apply, of course, only to fractures of the long bones, and especially to fractures of their shafts ; for in the short and flat bones such an occurrence is not without a certain degree of frequency. There is reason to believe that many of the so-called cases of transverse fractures of the shafts of the long bones are in reality oblique fractures, approaching more or less closely to the horizontal line, and yet not strictly falling within it. There are few practitioners, I imagine, who will not coincide with me in this view,

and who, like myself, have not had frequent occasion, upon further and more thorough exploration, to correct their diagnosis in cases of this description. If the question were one solely of a speculative nature, it would be of little consequence; but when its practical bearing is considered, it is impossible to lay too much stress upon it. As it will, however, be again adverted to in speaking of the treatment of fractures, nothing further need be said respecting it here. The annexed cut, fig. 417, conveys a good idea of an oblique fracture.

Fig. 417.

Oblique Fracture of the Forearm.

Longitudinal fractures are extremely rare, and are nearly always produced by gunshot violence. They are chiefly met with in the humerus, femur, and tibia. The fracture occasionally extends nearly through the entire length of the shaft of a bone; but generally it is not more than a few inches long. Now and then a fissure of this kind, after having passed a certain distance, runs off in an angular direction towards the surface of the bone, where it terminates, as in fig. 418. A longitudinal fracture sometimes occurs at the inferior extremity of the humerus, and also, but more rarely, at the lower end of the femur, separating one of the condyles of these bones, or even both of these protuberances, especially if there be at the same time a horizontal or oblique fracture a short distance above the corresponding joint. A longitudinal fracture is occasionally met with in the patella. Bone fissures, which are often, if, indeed, not generally extremely difficult of diagnosis, are occasionally compound, and are then usually of a very serious character, evidently from exposure of the medullary canal, as they are very liable to be followed by erysipelas, pyemia, osteomyelitis, and death.

Fig. 418.

Longitudinal and
Oblique Fracture.

The extremities of the fragments of a broken bone exhibit much diversity in regard to their form and size; in general, one is much larger than the other, as well as more sharp, rough, and irregular, as in fig. 419. In the majority of cases, they have a ragged, serrated, or denticulated appearance, the projecting pieces of one end corresponding with the depressions in that of the other. This arrangement, which is produced by the irregular division of the osseous fibres, bears no little analogy to that which occurs in the edges of a lacerated wound. The truth is, to carry out the analogy still further, an oblique fracture is nothing but a lacerated wound of the osseous tissue, which presents the same difficulty in regard to its perfect coaptation and speedy reunion as a similar lesion in the skin and muscles. The irregularities upon the extremities of the fragments are often sadly in our way, offering a great obstacle to the successful reduction and subsequent maintenance of the parts. Sometimes, indeed, the projecting pieces are so long and sharp

Fig. 419.
Appearances of the Ends of the Fragments.

as to pierce the integument, or require to be sawed off before the bone can be properly set. Such an occurrence is not uncommon in fractures of the tibia, and it is also witnessed, although less frequently, in the femur, radius, and clavicle.

Sometimes the fracture is *impacted*, the end of one fragment being forcibly driven into the other, so as to be, as it were, interlocked. Such an occurrence, of which fig. 420

affords an excellent illustration, can only arise, as a general rule, in those bones which contain an extraordinary amount of areolar substance, as the head of the humerus, the neck of the thigh-bone, and the lower extremity of the radius.

As a bone may give way at any part of its extent, at its middle, or at either end, it follows that the two fragments are rarely of the same length; instead of this, there is often a most marked disparity, as is exemplified in fractures of the extremities of the long bones, as the femur, in which, especially in fractures of its neck within the capsular ligament, the superior fragment is sometimes hardly an inch and a half in length, while the other is perhaps upwards of a foot and a quarter. Fracture of the olecranon affords a similar illustration. Such an occurrence is not without its influence in regard to the treatment and final issue of the lesion; for the nearer, as a general rule, the length of the fragments corresponds, the easier, other things being equal, will it be to maintain their apposition, and to secure prompt and perfect union.

Fig. 420.

Impacted Fracture of the Neck of the Femur.

A fracture may be single or multiple; that is, a bone may break at one or more places, sometimes as many as three, four, or even five; in other words, it may literally be crushed and comminuted. Such lesions are generally the result of inordinate violence, and are, therefore, very liable to be followed by serious consequences; often, indeed, by loss of limb and life.

In fractures of the leg and forearm, affecting both bones, it is extremely rare to find the injury situated on the same level; on the contrary, there is generally a considerable distance between the two fractures, amounting, according to my observation of numerous cases, ordinarily to from one to two, three, and even four inches. The interval is usually considerably greater in the leg than in the forearm, probably because of the greater inequality in the size of its two bones. What the cause of this occurrence is it is not easy to determine; but it may be supposed that it is due mainly, if not entirely, to the manner in which these pieces are respectively articulated to the wrist and ankle joints, in consequence of which the violence occasioning the lesion is transmitted more forcibly along one bone than the other, thereby compelling the former to yield before the latter. Thus, as the tibia is more intimately connected with the foot than the fibula, it follows, if this explanation be correct, that it ought to break lower down than the fibula, and this, I believe, is what usually happens, although there are many exceptions.

Fractures occur at all periods of life. During delivery, the bones of the arm and leg are occasionally broken in rude attempts at extraction. An infant, four weeks old, was brought to me on account of a fracture of the shaft of the right femur, caused two days previously by a child rolling over it in bed. The thigh was much swollen, and at least an inch and a half shorter than the sound one; all the extension and counterextension that I could make with my hands failed to restore it to its normal length. Fractures occasionally occur in the foetus in the womb. Chaussier met with a remarkable example of this description, in which each of the long bones had suffered more or less from these lesions, some of which were recent, others beginning to unite, while others were consolidated. The infant survived its birth only twenty-four hours. Analogous cases have been reported by other observers. In very young children the bones, owing to their softness and flexibility, instead of breaking, are very apt to bend, or give way at their epiphyses; in elderly subjects, on the contrary, they are very light and brittle, from the rarefaction and fatty degeneration of their substance, and are, therefore, extremely liable to yield under the slightest violence. Thus, a fracture of the neck of the femur within the capsular ligament is often produced by a mere twist of the thigh in bed, by entangling the big toe in a fold of the carpet, or by stepping off the curbstone.

Statistics have been collected which show that fractures of the upper extremity before the end of the fifth year occur with nearly equal frequency in both sexes; between this period and the fiftieth year they are most common in the male, and after the fiftieth year in women, owing to the remarkable frequency of fractures of the lower extremity of the radius and of the neck of the femur. Children are particularly liable to fractures of the clavicle, and to separation of the condyles of the humerus.

Causes.—The causes of fractures are divisible into predisposing and exciting; the first having reference to the part and system, or to local and constitutional circumstances, the second to external violence and muscular action.

The conformation, situation, and office of certain bones are so many predisposing causes

of fracture. Thus, as was before stated, the long bones, which are the great levers of locomotion, and which, in consequence, are constantly under the influence of large and numerous muscles, are much more subject to this accident than the short or flat bones, which are more passive in their character, as well as more closely articulated together, so that any force that may be communicated to them is more easily broken. The body of the scapula is seldom broken, because it is not only thickly covered by muscles, but, having no fixed point below, it is incapable of being injured by any shock transmitted by the hand, elbow, or shoulder. The acromion process, however, owing to its exposed situation, is not unfrequently fractured; while the coracoid process, protected by the deltoid, clavicle, and head of the humerus, rarely suffers from this cause. The radius, being articulated with the hand, is more liable to break than the ulna; the fibula, owing to its slender form and brittle texture, is oftener broken than the thick and heavy tibia; and every surgeon knows how very prone the collar-bone is to fracture, its exposed situation, the peculiarity of its conformation, and its connection with the sternum and scapula, rendering it particularly obnoxious to this occurrence.

Of the influence of age, in promoting the occurrence of fracture, mention was made in a previous paragraph. As life advances the bones not only become more brittle, but the muscles, the active agents of locomotion, lose their elasticity and suppleness, thus rendering persons more liable to falls, and, consequently, more prone to the accident in question.

Various diseases or states of the general system are usually regarded as predisposing causes of fracture. Of these, the most common are syphilis, carcinoma, sarcoma, scurvy, rickets, and osteomalacia.

A *syphilitic* state of the system, involving the skeleton, may so affect some of the bones as to render them abnormally fragile, and predispose them to this occurrence, as in the case of a man, thirty-one years of age, whom I attended for a fracture of the body of the right humerus, caused a short time previously, by throwing a small chip at a dog. He was perfectly well at the time, with the exception of some nocturnal pains in the arm and forearm. He had had primary syphilis seven years previously, and had been treated with mercury. The bone united in five weeks.

Carcinoma, as stated in a previous page, may so alter the osseous tissue as to render it preternaturally brittle, and cause it to yield under the slightest accident. Such an occurrence, indeed, is probably not so uncommon as is generally supposed. I have myself, however, seen only one instance of it. The patient was a lady, seventy-three years old, from whom I had removed, nine months previously, the left mammary gland, on account of scirrhus, under which she had labored for nearly three years. The wound healed kindly, but, some time after, the disease reappeared at the cicatrice, and gradually carried her off, not, however, before she had become extremely emaciated and bedridden. During the last month of her life, she complained of almost constant pain in the right thigh, deep-seated, and particularly severe at night; and three days before she expired, in an attempt to turn in bed, the femur gave way immediately above its middle. The limb was free from swelling and discoloration. No carcinomatous matter could be detected in the affected bone, which was quite soft, humid, and brittle, for some distance above and below the seat of fracture.

Sarcoma, especially when it takes its rise in the medullary structure of a bone, is often followed by fracture, the affected bone frequently giving way under its own weight, or under the most trivial accident.

Of the influence which *scurvy* exerts upon the osseous tissue, in predisposing it to fracture, the modern practitioner has little opportunity of judging, as the disease at the present day seldom appears in that violent form which characterized it in former times. As described by the older writers, it was often attended with the most horrible ravages, in which the skeleton not unfrequently participated, the synovial membranes, cartilages, and ligaments being ulcerated, and the epiphyses separated from the bones.

There are certain states of the skeleton, including *rickets*, in which the bones are so very brittle as to break under the most trivial injury. Cases are recorded in which from these and other causes, nearly every one of the long bones was broken, not only once, but a number of times. What is remarkable in these cases is that recovery is usually quite as rapid as in ordinary fractures. My collection contains a part of the skeleton of an old woman, who, in falling from a third-story window upon the pavement below, received not less than eighty-three fractures, involving the ribs, vertebræ, the scapula, the bones of the pelvis, and most of the bones of the extremities.

In *osteomalacia* fractures are sufficiently common in all parts of the skeleton, especially in the long bones of the extremities. In this disease the osseous tissue parts with its

earthy salts, and is rendered so soft and brittle as to give way under the slightest injury; often, indeed, under mere muscular contraction.

Charcot has reported a case of locomotor ataxia in a woman who suffered from numerous fractures of the femur and of both bones of the forearm. It is highly probable that diminished nerve power not unfrequently acts as a predisposing cause of such lesions.

Gout and *rheumatism* are sometimes enumerated as predisposing causes of fracture, and the following case, which I saw with Dr. Metcalf, would seem to countenance the possibility of such an occurrence. The patient, a common laborer, aged thirty-two, had always enjoyed good health until two years and a half before, when he was attacked with articular rheumatism, affecting the principal joints, first of the superior, and then of the inferior extremities, where it had continued for the last twelve months. The only cause which could be assigned for his suffering was exposure to cold and fatigue in a pork-house, where he had worked for fourteen successive winters. In December, 1855, he broke his thigh-bone, at the junction of the lower with the middle third, while pulling off his boot with his hands, the foot being at the time bent at a right angle with the leg. No pain or swelling followed the accident. The most remarkable feature in the case, when Dr. Metcalf first saw it, was the imperfect aëration of the blood, as indicated by the livid state of the face; the bowels were torpid, the tongue was coated, and there was considerable emaciation, but no disease of the heart and lungs. No chalky deposit existed in the joints and there was, so far as could be ascertained, no syphilitic taint. At the end of a month and a half, the parts being united, the dressings were removed, and the man was permitted to walk about on crutches. A week after this, he struck the affected thigh slightly against the rail of the bed, fracturing the bone at its upper third. Union took place within about the same time as before, the quantity of callus in each instance being uncommonly large.

The osseous tissue is sometimes remarkably *brittle* without any obvious cause. A gentleman, a patient of mine, fifty-four years of age, broke the right femur near its middle in the act of drawing off his boot, the leg being at the moment placed over the other. He heard a loud noise, and the limb became immediately useless. He had labored for a number of years under diarrhœa, but was in other respects well. At Guy's Hospital, London, a similar case occurred in a healthy man, of temperate habits, while engaged in raising his leg across the other to look at the sole of his foot.

The *exciting causes* of fracture are two, external violence and muscular contraction. The former, which is by far the more common, may act upon a bone either directly, or indirectly, through some other bone. In the first case, the force is applied to the bone itself, as in fracture of the jaw from the kick of a horse, or in fracture of the leg from the passage of the wheel of a carriage. Most fractures are of this description, and they are, therefore, generally complicated with more or less injury of the soft structures. In the other case, the force, instead of being applied immediately to the bone, is transmitted to it through another bone, or perhaps a chain of bones. It is in this way that the radius is so frequently broken just above the wrist by falls upon the hand, the force being concentrated upon its extremity, in consequence of the manner in which it is articulated with the carpus, while the ulna, which is but slightly connected with it, generally escapes. Fracture of the clavicle affords an instance of a bone being broken by indirect mechanical violence operating at two opposite points. Thus, in falls upon the shoulder, the sternal end being impelled by the weight of the body, and the acromial end by the object against which it strikes, the bone, acted upon by the two forces, gives way at its weakest part, which is usually about its middle. When a bone is very brittle, the slightest external violence may be sufficient to break it. In old people, the neck of the femur is frequently fractured by the merest twist of the limb in bed, or by stepping carelessly out of bed upon the floor.

A lady, eighty years of age, a patient of mine, while apparently in excellent health, broke her thigh bone in a fall in walking across her room. Fractures occasionally occur during parturition from violence inflicted upon the child by the accoucheur, or from the pressure exerted upon it by the contraction of the uterus.

It is not often that a bone is broken by muscular action, and yet such an accident is not, perhaps, as uncommon as is generally imagined. I have myself met with several examples of it. In three, the subjects were remarkable for their health and muscular development, and the fracture in each was produced while they were engaged in feats of strength, in which the elbows were planted firmly upon a counter, and the hands interlocked with each other. While the muscles of the arm and forearm were in a state of the utmost tension, the humerus snapped off suddenly, with a loud noise; in two cases at its

middle, and in the other at its inferior extremity. In another case, the fracture, also seated in the humerus, was caused by throwing a small chip at a dog. In this instance, alluded to in a previous paragraph, the bone had suffered for a considerable time under nocturnal pains, and had, no doubt, been rendered brittle by the effects of the syphilitic virus. The patient, who was thirty-one years of age, was otherwise in good health, but the muscles of his arm were rather soft and flabby. Dr. Hewson Bache has related to me the particulars of the case of a lady, ninety-seven years old, who broke her humerus in the act of throwing the arm about. She died seven weeks after the accident, without any union of the fracture.

Mere muscular contraction is sometimes sufficient to break the femur, as in the case of an eminent physician of Buffalo, who fractured this bone in the act of throwing a tenpin ball. A similar accident occurred in this city, in a gentleman, aged fifty-two, apparently in the most perfect health at the time. The femur gave way a short distance below the great trochanter, at a moment when the limb was strongly rotated upon its axis. Dr. Lente has recorded the case of a boy, twelve years of age, who broke both his thigh-bones during a severe epileptic convulsion. The patella and olecranon are frequently fractured by the action, respectively, of the extensor muscles of the thigh and arm.

From some of the above cases it is evident that a diseased state of the bone is not at all necessary to the production of this accident by muscular contraction, although such a change is perhaps generally present at the time of the fracture, and, therefore, deserves to be considered as a predisposing cause of it.

2. SIMPLE FRACTURES.

The symptoms of simple fracture may be considered, first, in relation to the broken bone itself; secondly, in relation to the soft parts; and thirdly, in relation to the constitution.

So far as the affected bone is concerned, there are only three symptoms which are at all reliable as evidences of the existence of fracture, namely, crepitation, deformity, and preternatural mobility.

Crepitation is the peculiar noise that is caused by rubbing the two ends of the broken bone against each other, and is always, when well marked, characteristic of the nature of the injury. In general, it can be both heard and felt. In order to produce it, it is necessary that the ends of the fragments should be at least partially in contact, and hence, to effect this object, the surgeon is often obliged, as a preliminary step, to extend and counter-extend the affected limb. For this reason it is always absent in impacted fractures, while in fractures of the leg and forearm, involving only one of the bones, it is usually very faint and indistinct from the difficulty of moving the broken pieces upon each other. Much swelling, great depth of tissue, or the interposition of blood, muscle, or other matter may also obscure the crepitation.

Deformity, although not invariably present, is generally one of the most prominent symptoms of fracture. It occurs in different forms, as in shortening, or in angular displacement, usually at the time of the accident, the cause which produces the fracture being also the cause of the distortion. Occasionally, however, it does not come on until several hours, or, perhaps, even several days after; as, for example, in a partially impacted fracture of the neck of the thigh-bone, in which the patient may be able to walk some distance, and yet the limb retain its normal shape. The degree and character of the deformity are greatly influenced by the nature and situation of the fracture. Thus, the more oblique the fracture is, the greater, as a general rule, will be the displacement of the ends of the fragments, and, consequently, also, the distortion of the limb. Sometimes, as in fracture of the patella, the olecranon, and calcaneum, the deformity manifests itself by a vacuity or hollow at the natural situation of the bone, and by an unusual protuberance upon the lower part of the thigh, arm, or leg, caused by the separation of the upper fragment by the action of the extensor muscles. Finally, the deformity may be much increased by extravasation of blood, or by effusion of serum and lymph consequent upon the resulting inflammation.

Preternatural mobility is, next to crepitation, the most important and reliable symptom of fracture. There are few instances in which it is wholly absent, while in the great majority it exists in a well-marked, if not in a high, degree. It usually appears immediately after the occurrence of the accident, and continues, to a greater or less extent, until the completion of the consolidation of the fracture. In the impacted fracture it may be entirely wanting, or remain absent until the ends of the fragments are unlocked. In fracture of the leg and forearm, involving only one bone, the degree of mobility is some-

times very slight, the sound bone impeding, or altogether preventing, the motion of the affected one.

In every fracture produced by external violence, whether applied directly or indirectly to the part, there must, of necessity, be a certain degree of contusion of the soft structures at the seat of the injury. It may be limited to the skin and subjacent connective tissue, or it may extend deeper, and involve the muscles, aponeuroses, vessels, nerves, periosteum, and even the bone itself. In consequence of this occurrence, there is not unfrequently a considerable effusion of blood beneath the skin, and in the connective tissue of the muscles, causing distension and sometimes discoloration. For the same reason, there is generally a good deal of pain, often of a sharp, spasmodic character, which is aggravated by the slightest motion of the parts, and by every attempt at exploration. It has its seat rather in the soft structures than in the affected bone, although the latter generally participates in it, and by the sharpness of its extremities frequently increases its severity. A short time after the accident, swelling usually sets in, and often proceeds to a considerable height, its degree being greatly influenced by the amount of injury sustained by the soft parts, by the motion to which the fractured bone is subjected, and by the state of the system at the time of the accident. As a general rule, it may be affirmed that the pain and swelling are less in fractures produced by muscular contraction than in fractures caused by mechanical violence, whether directly or indirectly applied.

Inability of motion in the affected bone, and in the portion of the limb articulated with it, is generally a prominent symptom. Cases, however, occur in which it is either very slight or entirely absent. In an impacted fracture of the thigh-bone, for instance, a patient will sometimes walk a considerable distance without the slightest assistance even from a cane, and in fracture of the clavicle I have repeatedly seen him carry his hand to his head, and even circumduct the arm.

Another symptom, consequent upon fracture, is spasm of the muscles at the seat of the injury; it is most common in nervous, irritable persons, and generally comes on within a short time after the accident. When severe, as it frequently is, it constitutes a source of great suffering. It is aggravated by motion and inflammation, and may continue, with more or less interruption, for several hours, if not days.

Finally, the patient often experiences a sense of numbness in the affected part, reaching frequently to the distal extremity of the limb. This may be caused either by the injury sustained by a nervous trunk at the time of the accident, or by the compression of the soft parts by extravasated blood or by the ends of the broken bone. Sometimes it does not arise until inflammation has supervened, and then it is generally owing to the presence of an unusual quantity of serum and lymph.

The amount of constitutional disturbance in fracture varies, in different cases, from the slightest exaltation of the normal action to the most intense excitement, depending mainly upon the nature of the fracture, the degree of injury sustained by the soft parts, and the state of the system at the time of the accident. In very many cases there is an entire absence of traumatic fever, while in others it is present in a very high degree, the pulse being strong and frequent, the countenance flushed, the skin hot and dry, the thirst intense, the appetite and sleep much impaired, if not totally suspended, and the temperature above 100° Fahr. In the more violent forms of fracture, the patient often experiences severe shock, from which he may not fully recover for many days, or which may even terminate in death. Whenever there is much constitutional disturbance, the affected limb will be apt to be in a high state of inflammation, the parts be hot, swollen, painful, and, at times, even covered with small vesicles, such as a heedless observer might easily mistake for the phlyctenulae which so often announce the occurrence of gangrene. Pyemia is uncommon in simple fractures.

Displacement of the Ends of the Fragments.—Displacement of the fragments shows itself, as already stated, in two principal directions, the longitudinal and horizontal. Of these, the former is by far the more common, as it is present, to a greater or less extent, in nearly all cases of oblique fracture, in whatever portion of a bone occurring. It is produced by the overlapping of the extremities of the fragments, the lower being drawn above the upper, or the one riding over the other, as it is sometimes expressed. The extent of this form of displacement varies from the slightest possible change in the length of the affected bone to two, three, and even four inches, which may be regarded as its maximum. It is generally most conspicuous in fracture of the femur and humerus, while in fracture of the forearm and leg, affecting only one bone, it is either very slight or totally wanting. Finally, the displacement may be lateral, or posterior, according to the nature of the exciting cause.

In the horizontal displacement, the lower fragment may form an angle, more or less acute, with the superior, thereby giving the bone an arched appearance; or, the two pieces remaining in contact with each other, the inferior one may perform a rotary movement, while the other continues perfectly stationary. In some cases, as in fracture of the lower end of the radius, there is often considerable lateral displacement, and similar phenomena are apt to occur in fracture of the tibia and fibula at or near the ankle-joint.

The causes of displacement are muscular action, mechanical violence, and the weight of the limb connected with the broken bone. Of these the first is the most common, and it need hardly be added that a knowledge of the fact is of the greatest practical importance in regard to the proper management of the injury. In some instances the displacement is entirely produced by the vulnerating body. Thus, in fracture of the nose, the blow which inflicts the injury also displaces the fragments. The wheel of a carriage passing over the leg may not only break its two bones, but likewise cause great deformity by forcing asunder their extremities. Finally, the displacement may be occasioned by the weight of the limb connected with the injured bone, as in fracture of the clavicle, in which the outer fragment is drawn downwards and inwards by the weight of the shoulder and arm.

Diagnosis.—The most valuable symptoms of fracture, diagnostically considered, are, crepitation, deformity, and preternatural mobility. The coexistence of these symptoms is unmistakably denotive of the nature of the accident, but, unfortunately, they are not always associated; one or even two may be absent, and, therefore, a case that ought to be treated in the most prompt and decisive manner, may, for the want of a correct appreciation of its character, be either entirely neglected, or, at all events, grossly mismanaged. Besides, the symptoms here enumerated may be simulated by other accidents, especially dislocation, and certain affections of the joints.

The crepitation of fracture is sometimes imitated by the grating produced by an effusion of plastic matter into a joint, the sheath of a tendon, or a synovial bursa; and the difficulty may be still further increased, if, under such circumstances, the suspected fracture is situated near a large articulation. In general, however, it will be sufficiently easy to distinguish between them by a consideration of their respective characters. In fracture, the crepitation can be both felt and heard; it is dry, coarse, or rough, resembling the sensation and noise produced by rubbing two unequal surfaces against each other. The crepitation from plastic matter, on the contrary, is of a finer quality, or more faintly marked, and may be likened to the feel and noise caused by gently rubbing over each other two pieces of sole leather; in a word, it lacks the roughness and distinctness of the other. Moreover, it must be remembered that it is never present until after the occurrence of inflammation, whereas the other always exists the very moment after the accident. Crepitation, it is true, might be produced as a consequence of previous disease, and the possibility of such an occurrence should not be lost sight of in our examinations. Finally, when the case is obscure, the crepitation may sometimes be detected by the aid of the stethoscope, especially when the bone is thickly covered by muscles, as in fracture of the neck of the femur within the capsular ligament, or in fracture of the ribs in corpulent subjects. This mode of examination was originally suggested by Lisfranc, but as the expectations held out by him have not been realized, few practitioners of the present day resort to it.

The deformity in fracture manifests itself either in shortening, in lateral displacement, or, as not unfrequently happens, in the two united. Elongation is never present, in which respect fracture differs from certain forms of dislocation, in which lengthening is a prominent symptom. The degree of shortening varies from a few lines to several inches, and is, therefore, an event of much diagnostic value. It may exist from the commencement of the accident, or it may not show itself until some time after its occurrence, being materially influenced by the action of the muscles, and the nature of the treatment. Whatever the degree of the deformity may be from these causes, it may always be effectually removed by extension and counterextension, either alone or aided by pressure; but as soon as these forces cease to operate, it is usually immediately reproduced, which is not the case in dislocation. Here, the reduction having been effected, the parts generally retain their relations until some new cause produces a new displacement.

Too much stress cannot be placed upon preternatural mobility as a sign of fracture. Next to crepitation, it is unquestionably the most important diagnostic symptom. There may be unnatural latitude of motion in a dislocation, but this can only happen when the accident is attended with extensive laceration of the ligaments of the joint; in ordinary cases there is either an absence of motion, the displaced bone being firmly fixed in its

new position, or the motion is so slight as to bear only a faint resemblance to that observable in fracture.

The "physiognomy," or general expression of the affected parts, as in fig. 421, often affords valuable diagnostic aid. The deformity, for example, of the hand and wrist, in fracture of the lower extremity of the radius, the eversion of the toes in intracapsular fracture of the femur, and the shortened and retracted appearance of the arm in fracture of the humerus, are generally unmistakable evidences of the nature of the accident. The manner in which the patient inclines his head and supports the elbow and forearm in fracture of the clavicle, is too significant to be overlooked by any one who has ever witnessed it. The peculiar aspect and attitude of a broken thigh, conjoined with the utter helplessness of its muscles, or the absence of all voluntary power, are signs which seldom admit of misinterpretation.

Fig. 421.
Fracture of the lower End of the Radius.

In fracture without displacement there is sometimes a persistent soreness or tenderness on pressure with the finger at the site of the injury, which, with proper care in the examination, may lead to useful diagnostic information. I have seen this repeatedly in fracture of the clavicle in children, and also in fracture of the bones of the forearm in fat, elderly subjects, and, therefore, look upon it as a most valuable symptom where the ordinary means of recognition fail.

The pain, swelling, and loss of function, present in suspected fracture, are of no practical value, as similar phenomena are produced by other injuries, as contusions, wounds, sprains, and dislocations. Their occurrence being wholly accidental, must, therefore, not influence the surgeon in his attempt to form a correct estimate of the true nature of the case, or the relative value of the symptoms of this and analogous affections.

In fractures of the inferior extremities accurate measurement must not be neglected, similar to those indicated in a former chapter. A very safe and excellent plan is that suggested by the late Professor R. O. Cowling, of Louisville, Kentucky. The patient lying upon a hard, level surface, and the parallelism of the iliac spines and the proper extension of the limbs being looked to, a tape is carried from the umbilicus around a corresponding part of the sole of each foot, and back again to the point of departure. The reference, however, between the two measurements thus obtained represents twice the amount of difference which exists in the length of the limbs, a circumstance that must be borne in mind in determining the actual amount of shortening. Ingenious contrivances for ascertaining the relative lengths of the lower extremities have been devised by Dr. H. Z. Gill, of Illinois, Dr. John Bartlet, of Chicago, Dr. Morton, and several other surgeons.

Mode and Time of Examination.—Although the symptoms which have now been described will generally be sufficient, along with a careful consideration of the history of the case, to enable the surgeon to determine the diagnosis of this lesion, especially if he takes the trouble of comparing them with the symptoms of other accidents, it will, nevertheless, be proper, in concluding these remarks, to say a few words respecting the manner of conducting the examination of the affected parts, as the ultimate issue of the case will greatly hinge upon this circumstance.

Few practitioners know how to examine a broken limb. They take hold of it as if they were afraid of causing suffering, and it is, therefore, not surprising that the result is often most disastrous. I am far from wishing to be understood as being an advocate of rough surgery—on the contrary, no one deprecates it more than I do—and yet there are times and circumstances when the best interests of the patient demand that he should be most thoroughly examined, no matter what amount of pain he may be compelled to undergo. But there is no longer any need of such infliction now that suffering can be prevented by anæsthesia. The patient being rendered insensible, perquisition is performed at the surgeon's leisure, slowly and deliberately, and with an eye to the ultimate result, not forgetting self. The sooner such manipulation is instituted the better, for there will then be less likelihood of inflammatory swelling and other obstacles calculated to embarrass our progress or to obscure the diagnosis. Fractures of the shafts of the bones will rarely offer any difficulty, inasmuch as their symptoms are generally so well marked that the most casual inspection will be sufficient for their detection. But it is different when the lesion involves their extremities. Here the most laborious and painstaking

examination sometimes hardly enables the practitioner to form an accurate judgment respecting the real nature of the injury. Under such circumstances, therefore, he must not content himself with one or two trifling explorations; he must handle the parts again and again, until he has thoroughly established the diagnosis.

For the reason already assigned, the parts should always be examined as early as possible after the infliction of the injury, but no exception should, in my judgment, be made even when some time has elapsed, and a good deal of swelling has supervened; for it is impossible that a broken bone, or the parts by which it is covered, should do well so long as its extremities are displaced, and thus permitted to fret, irritate, and, perhaps, prick the muscles and other structures in contact with it. The sooner, indeed, the parts are restored to their natural relations, the more likely will they be to do well, and to escape the ill effects of inflammation. There are instances, however, where, as may be supposed, immediate interference might prove highly prejudicial, using the term immediate here with reference to the surgeon's first visit. The patient may have been neglected, or his attendant may have mistaken the nature of the case, and in this manner several days may have passed uselessly away. The limb is now found to be very much swollen, extremely painful, and intolerant of the slightest manipulation, nay, perhaps, in an erysipelatous condition. To make an elaborate examination under such circumstances would be very injudicious, as it could not fail to aggravate the morbid action, and, perhaps, urge on gangrene. The hand is withheld; the limb is placed in an easy position, and antiphlogistics, both local and constitutional, are freely plied; when action has sufficiently abated, but not until then, the proper examination is effected, and the diagnosis, if possible, established.

The mode of conducting the examination varies. In the upper extremity the surgeon will usually be able to get on without any assistance, but in fracture of the thigh and leg it is often necessary to make extension and counterextension while the parts are subjected to methodical manipulation. When there is marked displacement, the merest touch of the hand will generally suffice to detect the nature of the lesion; whereas, under opposite circumstances, the nicest digital exploration may be required. In general, it will be necessary to make pressure and counterpressure at the seat of the injury, and to rotate the portion of the limb below the fracture upon its axis. In this manner, especially if proper extension has been effected, the ends of the fragments, brought into close contact, may be made to yield the friction-sound, previously described, and at the same time display the full extent of their mobility. Another procedure is to grasp the two extremities of the suspected bone, and then, while the superior one is firmly held with the thumb and finger, to roll the inferior upon its axis. If both parts move together, the probability is that there is no fracture; whereas, if the lower move, and the upper remain stationary, there can be no doubt of the fact.

Mode of Repair.—A fracture is repaired precisely upon the same principle as a wound of the soft parts, the only difference being the superaddition of carbonate and phosphate of lime, or the earthy constituents of bone. In order, however, to understand the matter thoroughly, it is necessary to study it with reference to the situation and disposition of the ends of the fragments of the broken bone, as the rapidity and perfection of the cure are greatly influenced by the manner in which they are arranged and held together during the treatment. The more perfect the apposition is, the more complete, generally, other things being equal, will be the reunion. For practical purposes, the whole subject of repair may be considered as consisting of four stages.

The first stage, which, on an average, in the adult, extends from the first to the sixth or eighth day, is one altogether of preparation, in which nature clears away the rubbish, and places the ends of the fragments in a suitable condition for the process of repair, properly so called. The blood which was extravasated at the moment of the accident, at and around the seat of the fracture, is, in great degree, if not entirely, absorbed; the inflammatory products, especially the intermuscular, are also disposed of; the swelling subsides, the pain disappears, and there is no longer any tendency to spasmodic action, the muscles having become calm and quiet under their new relations. Any traumatic fever that may have been present will also be found to have vanished. Thus the part and system have happily passed through the preliminary stage of the reparative process.

If the parts be examined at the beginning of the second stage, it will be seen that the ends of the broken bone, as well as the periosteum, and the other soft parts in their immediate vicinity, are abnormally red and injected, and covered with a layer of embryonic cells, resembling very much, in color and consistence, pale currant jelly, or a thick solution of isinglass. It is usually most abundant upon the surface of the bone, and is often

sufficient to lift up the periosteum ; a considerable quantity is also generally seen between the periosteum and the muscles, and even among the muscles themselves, all these structures being more or less actively engaged in the process of repair. A similar tissue, but usually less abundant, is formed by the medulla of the central canal, the lining membrane of which is also in a state of inflammation, as is evinced by its discolored and injected condition. In the latter part of this stage, which lasts from the eighth to the sixteenth, eighteenth, or twentieth day, the granulation tissue, which differs in none of its properties from that which serves to unite a recent wound, becomes gradually more and more firm, until at length it assumes the consistence of a semisolid substance.

The third stage is characterized by still further changes in the consistence of the newly-formed tissue, and by its gradual conversion, first into fibro-cartilage, then into cartilage, and finally into bone ; or, more correctly speaking, cells are developed in the new substance, into which the osseous granules are deposited, the whole process bearing the closest possible resemblance to that which takes place in the formation of the original bone. It should, however, be stated that while the embryonic tissue which surrounds the surface of the broken bone is first transformed into cartilage, the mass of cells which result from the proliferation of the medulla, and which form the central plug, are converted into bone without the intervention of cartilaginous tissue. The period at which the osseous matter begins to be developed in the adult varies from the eighteenth to the twenty-fifth day, its appearance and progress being influenced by numerous local and constitutional causes, to be described under another head.

The ossific process proceeding in the way now described, two layers of bony matter are formed, one lying upon the outer surface of the ends of the fragments, the other within the medullary canal, each extending some distance beyond the seat of fracture, as is seen in fig. 422. To these two strata is confided the office of temporarily supporting the fragments, or of holding them together until their ends are permanently united by osseous substance ; a circumstance which does not, as a rule, take place until several months later. To this

Fig. 422.

Fractured Tibia, with new Bone beneath the Periosteum, and within the Medullary Canal.

new formation the older pathologists applied the term *callus*, in consideration of its hardness, which, when the process of repair is completed, is fully equal to that of the original bone, which it also closely resembles in its structure. From its office, the outer and inner callus, or that which invests the broken bone and lies in its medullary canal, is now universally known as the temporary or provisional callus, while that which is placed between the two ends of the bone, and thus serves to cement them together, is designated as the definitive or permanent callus. The temporary callus is, figuratively speaking, nature's splint, or the means which she employs to support the fractured bone until the continuity of the fragments is reëstablished by the deposit and organization of osseous matter between their extremities.

Callus, after having gone through its various stages of development and growth, is always much harder than normal bone, or the bone which it serves to unite. Its density, which often approaches that of ivory, is essentially due to a disproportionate increase of earthy matter. In natural bone the quantity of animal substance varies, on an average, from fifty-five to fifty-eight per cent., whereas in the callus of a broken bone it hardly reaches forty-five. The quantity of carbonate of lime is more than twice as great as in the natural state, and there is also a considerable increase in the amount of phosphate of lime. The composition, density, and strength of callus vary, of course, in different pieces of the skeleton, and in different conditions of the system, as it respects the age and health of the patient.

As the first stage in the reparative process is one of preparation, so the last is one of completion ; reunion having been effected, nature now busies herself in removing whatever is redundant or superfluous, thereby fitting both bone and muscle for the resumption of their respective functions. The provisional callus, having ceased to perform its office as a splint, is gradually brought under the influence of the absorbents, the more superficial portions being taken away first, and afterwards the more deep, until the broken bone regains not only its original form and volume, but also its pristine smoothness, all evi-

dence of fracture disappearing, excepting, perhaps, a little seam or ridge corresponding with the line of junction of the two fragments. While these changes are going forward upon the exterior of the bone, nature is busy at work in its interior, disposing of the provisional callus in that situation, and thus restoring the medullary cavity to its normal condition. This can occur, however, only when there has been perfect apposition of the ends of the fragments; for, when the reverse is the case, the new bone remains permanently in the canal, as is shown in fig. 423, from a specimen in my collection. Any

Fig. 423.
United Fracture, showing the Condition of the Medullary Canal.

fibrous, cartilaginous, or osseous matter that may have been formed between the periosteum and muscles, or among the muscles themselves, is likewise removed as a substance foreign to the part, and, therefore, useless, if not positively prejudicial.

It will thus be seen that the fate of the provisional callus is precisely similar to that of the plasma which is effused between the edges of a wound, both gradually disappearing, as soon as their service can be dispensed with, or as soon as the parts have acquired sufficient firmness to enable them to maintain their connection. The period required for effecting these changes in a broken bone varies from a few weeks to several months, according to the circumstances of the case, more especially the age and health of the patient, and the nature of the treatment.

Such is a brief account of the several changes which attend the repair of bone in the more simple forms of fracture, when the ends of the fragments are thoroughly maintained in their natural relations. Under such circumstances there is but little need of provisional callus; the ends of the fragments soon inflame, and unite almost by the first intention. But it is seldom that a patient is so fortunate; on the contrary, the fracture being generally oblique, is subject to more or less displacement, thus compelling nature to provide a temporary splint by the formation of provisional callus. I do not believe, however, as has recently been so much insisted upon, that there ever is an entire absence of this kind of callus, however intimately the ends of the bones may be in apposition with each other. To prove the truth of this remark, it is only necessary to examine the numerous specimens of fracture of the skull and other portions of the skeleton in our museums; they will conclusively demonstrate that even the most simple fracture, unaccompanied by the slightest displacement, is seldom repaired without the development of a certain quantity of osseous matter upon its surface. At the same time it must be admitted that the provisional callus, in such cases, is very small, and that it bears no proportion to the enormous amount of substance that is so often formed when the ends of the bone are separated from each other. Under the latter circumstances, nature labors under great disadvantage, and is, therefore, obliged to make extraordinary efforts to effect reunion, which she can do only by the development of a large provisional callus. From these facts, then, we may deduce the general law that the quantity of new bone is always, other things being equal, in proportion to the contact of the ends of the fragments, being small when this is very accurate, and more or less large when it is imperfect.

When the ends of the bones are not closely approximated, their edges are gradually

Fig. 424.
Appearance of the Ends of the Fragments in an old Ununited Fracture.

rounded off by the absorbents, the opening in the medullary canal is closed by a shell of new matter, as in fig. 424, and a large provisional callus is formed for the more secure

protection of the fracture. The whole process is one of time and labor, not of speed and ease, as in the former case. When the ends are completely separated, but opposite, or nearly opposite, to each other, they are generally united by a bridge of new bone, extending from one to the other, and ultimately affording sufficient strength for the support of the weight of the body upon the affected limb, as in fig. 425, from a specimen in my cabinet, representing the humerus of a turkey. Or, instead of this, especially in elderly subjects, the junction is effected by fibrous, fibro-ligamentous, or cartilaginous matter. Finally, osseous union is not impossible when the extremities of the fragments overlap each other to an extent even of several inches, provided they are in contact; for in this case inflammation is established in the contiguous surfaces, followed, after a long time, by a large permanent callus. We see many curious specimens illustrative of this fact, although, in general, the union is ligamentous.

Fig. 425.

Fracture of the Arm-bone of a Turkey.

There are certain pieces of the skeleton in which in fracture provisional callus seldom, if ever, forms. Of this description are the olecranon, acromion, patella, and neck of the femur. Instead of uniting by osseous matter, as the other bones do, the cure is generally effected through the medium of fibrous, ligamentous, or cartilaginous substance, and the consequence is that the part commonly remains weak ever afterwards. Various causes conspire to produce this result, as the difficulty of maintaining the contact of the broken surfaces, and the inordinate secretion of synovial fluid, which, mingling with the effused plasma, thus impairs its vitality, and renders it unfit to become the nidus of bony deposit; but the most efficient one of all is the want of nourishment of the smaller fragment produced by the laceration of its nutrient vessels. Thus, in intracapsular fracture of the femur, the only connection between the upper fragment and the pelvis is by the round ligament, the arteries of which are altogether unequal to its proper support.

Treatment.—The leading indications in the treatment of fracture are to procure reunion and to prevent deformity. Before the manner of fulfilling these indications is discussed, it is proper to lay down certain rules for the transportation of the patient, and the mode of preparing his bed.

Fractures are often received by persons at a considerable distance from their homes, either on the road, in the field, or at some secluded building. This renders it necessary to carry them to their own houses or to some hospital, in order that they may undergo the proper treatment. In fractures of the superior extremity, clavicle, scapula, or ribs, the requisite dressings may be applied at once; or, if this is not convenient, the patient may either walk or ride, the suffering limb being supported in a sling; or, in the case of a broken rib, the body may be swathed with a long towel. It is only, as a general rule, in fractures of the inferior extremity, spine, or pelvis, that the patient will require to be carried, and the best way of effecting this, if the distance is not too great, is to place him upon a narrow door, a long shutter, or two pieces of board, supported by two cross-pieces, the ends of which are intrusted to four assistants, a pillow and comfort having previously been put under the patient's head and body. Or, instead of this, the transportation may be conducted upon an easy furniture-car, provided with a good mattress, and drawn slowly along in order to avoid jolting. Whatever mode be adopted, the limb should be temporarily splinted, and placed in as comfortable a position as possible, an intelligent person sitting by the patient's side, and rendering such aid as may be required on the way. In carrying him to his chamber, four assistants will generally be necessary, two to support the body, which they do by crossing their arms behind the trunk and interlocking their hands, and two for the lower extremities, the surgeon himself taking charge of the broken one.

It may be assumed as an axiom in surgery that no man with a broken thigh or leg can be treated successfully without the advantages of a suitable bed. Prompt attention should, therefore, always be given to this matter, in order that no injurious delay may arise. When we reflect upon the fact that in fractures of the lower limbs the patient is often compelled to remain in the recumbent posture for weeks together, and how difficult it is, in most cases, to maintain the requisite extension and counterextension, the force of this injunction cannot fail to be perceived in its true light. The essentials of a good fracture-bed are, first, firm, stout slats, instead of a cord or sacking bottom; secondly, a well-

constructed mattress of hair, moss, or cotton; and, thirdly, a hole in the mattress, opposite the buttocks, for the easy relief of the bowels, the opening being closed by a door of similar manufacture, and furnished with hinges and other appliances. If long confinement in one posture is necessary, or if the patient has been worn out by previous disease, an air-mattress may be required, in order to prevent bed-sores. If a sheet be used, the edges should be carefully pinned to the sides of the mattress, otherwise it will soon become rumpled, and a source of more or less annoyance, if not of great suffering.

It has been a much mooted question whether, as a general principle, a fracture should be set as soon as possible after its occurrence, or whether time should be allowed for the subsidence of the resulting inflammation. It appears singular that upon a subject so clear as this there should be any difference of opinion. It certainly requires no great knowledge of the nature of accidents to discover why such cases should receive the earliest possible attention; so long as the ends of the fragments are permitted to remain apart, their tendency inevitably must be to excite spasm and inflammation, thereby increasing the suffering of the patient and retarding his cure. Of this fact there can be no doubt, and, therefore, my plan is to treat every case of the kind as early as possible with the bandage and splint; applied, of course, not firmly, but gently and cautiously, simply with a view of giving support to the parts, and thus preventing further mischief from the sharp and projecting ends of the broken bone. It is difficult to imagine an instance to which such treatment would not be adapted. It might as well be expected that a man's limb would do well if it had a thorn imbedded in its muscles, as that it would be comfortable with two pieces of bone sticking in them. It is absurdity to think it could be otherwise.

When, in consequence of excessive inflammation, a fracture cannot be set at once, the limb should be maintained perfectly at rest, in the easiest possible position, and the parts kept constantly wet with lotions of lead and laudanum until the case admits of the application of the permanent dressing. This practice is nowhere more necessary than in fractures affecting the joints, which are always followed by more or less copious effusion of synovial fluid. To get rid of such fluid as soon as possible is a cardinal rule of treatment; and certainly no sensible surgeon would use any tight dressing so long as there is any considerable swelling of the soft structures.

Apparatus.—Before an attempt be made to set the fracture, it is necessary to provide the requisite apparatus for effecting its maintenance. The means which are employed for this purpose are splints, cushions, bandages, and adhesive strips.

Splints are made of various materials, as wood, trunk-board, leather, felt, gutta percha, tin, wire, and iron, according to the nature of the fracture, or the fancy, whim, or caprice of the practitioner. In fracture of the thigh and leg, especially in that form which requires permanent extension and counterextension, the best article is wood. In fracture of the superior extremity, particularly of the humerus and of the bones of the forearm, splints made of trunk-board generally fulfil every indication, as by a little manipulation, after immersion in hot water, they may easily be moulded to the form of the limb. A piece of thick pasteboard affords a good support to a broken jaw or finger. Unoiled sole leather, gutta percha, and felt, the latter being rendered stiff by gum shellac, make excellent splints, which are often used with much satisfaction in fractures both of the upper and lower extremities. Previously to applying them, they must be softened in hot water, the sharp angles and edges having been pared off with a knife. The tin case I have employed a great deal, especially in fracture of the humerus at the elbow, and of the tibia at the ankle, ever since I entered the profession. Iron splints, in the form of the double inclined plane, are sometimes used; and very good splints may be made of light wire and of perforated zinc. For fractures of the bones of the hand and fingers, carved splints are very serviceable.

An excellent splint may be made by filling the meshes of a piece of linen, muslin, or canton flannel with a thick solution of plaster of Paris in water, and then doubling the cloth upon itself as many times as may be requisite to obtain the proper strength, when it is immediately secured to the limb with a roller. The advantages of this apparatus are that it dries in a few minutes, forming thus almost instantaneously a firm, stiff shell for the broken limb, perfectly adapted to its inequalities, exceedingly light, indisposed to absorb discharges, and admitting of easy application and removal. The plaster splint was first employed in this country by Professor James L. Little, by whom it was introduced into the New York Hospital as early as 1861. It is rapidly coming into general use.

Felt splints, adapted to the different regions of the body, and put up in portable cases, have of late years been a good deal employed; they are very light and flexible, are not affected by cold or warm water-dressings, and are easily moulded to every inequality of the surface of the parts to which they are applied.

Fracture *cushions* are generally made in the form of small bags, stuffed with bran, fine chaff, cotton, wool, hair, moss, or any other soft material. They are designed to fill up the inequalities between the splints and the limb, and must necessarily vary in shape, length, breadth, and thickness, according to the exigencies of each particular case. Instead of cushions, simple pads or compresses are often used, especially in fractures of the superior extremities. For enveloping short splints, calico, muslin, or old flannel is employed; or, what I always prefer, glazed wadding. The same article or batting answers admirably for filling up the inequalities between the short splints and the affected limb. Bags filled with sand are sometimes very convenient and useful, especially in fractures of the leg and thigh. Stretched along the sides of the limb, they keep up steady, equable pressure, well calculated to prevent displacement of the fragments.

The fracture *bandage* is made of coarse linen or muslin, of sufficient strength to answer the purpose for which it is intended. Nothing is worse, or more likely to cause annoyance, than a thin, flimsy bandage. If the material is new, it must be washed before it is used, to rid it of its glazing, and the selvage is torn off to prevent it from exciting irritation, or producing welts in the skin. The bandage most commonly used is the ordinary single-headed roller, of a length and breadth suitable to the affected limb or part of the body to which it is to be applied. In fractures of the leg and thigh, especially complicated ones, the bandage of Scultetus may often be advantageously employed, as it can be easily undone and reapplied without any disturbance to the limb. It consists of numerous strips of the ordinary roller, of equal or unequal length, according to the size and shape of the affected parts, applied in such a manner that one overlaps another nearly one-half.

Too much caution cannot be observed in the use of the bandage in the treatment of fractures. It is an agent for good or for evil; for good, if applied properly; for evil, if applied improperly. Its object is twofold; first, to afford uniform compression of the limb, thereby preventing swelling and spasm; and, secondly, to retain the necessary apparatus. The application is always begun at the distal portion of the limb, and continued upwards some distance beyond the seat of the injury, care being taken not to interrupt the circulation, or, to inflict other mischief. If it be too slack to support the parts in a proper and uniform manner, it will be useless; if too tense, it will give rise to severe inflammation, swelling, and even gangrene. For the want of this precaution, many limbs are lost, and a still greater number rendered permanently useless.

The application of the roller to the surface of the skin in the treatment of fractures, has at the present day many opponents, on the ground that, when thus employed, it is liable, by its pressure, to embarrass the circulation, and predispose to the occurrence of gangrene. It is alleged that it is particularly objectionable when applied high up to the forearm when the limb is greatly flexed, or placed nearly at a right angle with the arm; or when, under similar circumstances, it is applied to the foot and leg. Any thing is liable to abuse, and it is certain that a roller, if improperly applied, may do a great deal of harm; a circumstance against which a judicious surgeon always carefully guards. If he has not sufficient confidence in his ability to use the roller, or the circumstances for its employment are inauspicious, the only rational plan is to dispense with its application as a covering for the skin.

Adhesive plaster, cut into suitable strips, is now universally employed in this country, as a means of making extension, in the treatment of fractures of the lower extremity, and nothing, certainly, could generally answer a better purpose. To this plan of treatment I called special attention, in my Treatise on the Diseases of the Bones and Joints, published in 1830, having a short time previously witnessed its good effects in the practice of the late Dr. Joseph K. Swift, of Easton, in a case of very oblique fracture of both bones of the leg, complicated with so much injury of the soft parts as to interfere effectually with the use of the garter and other extending bands. The man had suffered a great deal of pain, until his patience was almost exhausted, when trial was made with adhesive strips, carried along the sides of the limb towards the knee, their free extremities being tied below the foot, to the transverse block connecting the two splints. Great comfort was at once experienced, and the case progressed favorably from that time forward. Soon after, I had occasion to use adhesive strips in a case of my own, with results equally gratifying: I subsequently extended the practice with great advantage to the treatment of fractures of the clavicle, ribs, olecranon, and patella, as well as of the thigh and leg. Valuable papers have been published on this mode of management by Ellerslie Wallace, David Gilbert, John Neill, Josiah Crosby, and others. In a short article in the Philadelphia Medical Examiner for 1852, I also called attention to the subject, giving very

briefly the results of my experience up to that period. The importance of this agent, for the purposes here referred to, will be fully pointed out under the head of special fractures.

Coaptation and Dressing.—Everything having thus been provided, and the requisite number of assistants obtained, the surgeon proceeds to restore the broken pieces to their original situation; or, to use a common expression, to set the fracture. This may be done either by simple manipulation, or by pressure and counterpressure, or by this means aided by extension and counterextension. The former will usually suffice in fracture of the upper extremity, the jaw, and nose, while the latter will generally be required in fracture of the thigh and leg; in either case, the affected limb should be held as quietly as possible, not only during the adjustment of the fragments, but also during the application of the dressings. It need hardly be observed that these manipulations should be conducted in the most gentle manner, with an eye both to present comfort and future consequences. There is no department of surgery where the humane practitioner may exhibit his skill and sympathy to greater advantage than in this, or where his conduct will be more closely watched and commented upon than upon such an occasion.

There are several causes which may seriously interfere with, and sometimes even entirely prevent, the reduction of a fracture. Of these one is muscular contraction, induced by the irritated condition of their fibres, which, however, is generally easily overcome with the aid of an anæsthetic. Occasionally the obstacle is some foreign substance, as a piece of bone or a portion of muscle, accidentally interposed between the ends of the broken bone. Now and then the difficulty depends upon the presence of coagulated blood. The most common cause, however, of all is the shape of the extremities of the fragments. If these be denticulated, very sharp, notched, or uncommonly oblique, accurate adjustment and maintenance will be extremely difficult. In extensive comminution, as in certain multiple fractures, the obstacle to reduction is often very great, if not positively insurmountable, owing to the manner in which the fragments are wedged into each other and into the surrounding structures.

Extension and counterextension are always necessary in oblique fractures of the extremities, attended with displacement. By the term extension is understood the force which is required to draw the upper end of the lower fragment to a level with the lower end of the upper fragment, in order to place them in their natural relations; by counterextension, on the contrary, is implied the resistance which is employed to prevent the limb, or even the body, from being dragged along by the extending power. The extension is generally made upon that part of the limb which is articulated with the lower piece, and the counterextension upon that which is articulated with the upper. Thus, for example, in fracture of the shafts of the bones of the forearm, the extending power acts upon the hand, and the counterextending power upon the arm, while in fracture of the body of the humerus the two forces are respectively exerted upon the forearm and the chest; and so in regard to fracture of the inferior extremity. When but little muscular resistance is anticipated, as in a child or feeble person, the extension and counterextension may be applied directly to the two fragments, but at as great a distance from the seat of the injury as practicable. On the whole, however, the former method is decidedly preferable, as it is much less likely to irritate and worry the muscles.

In reducing a fracture, the parts must be put in the most favorable position for relaxing the muscles, and the extending forces applied in as slow and gradual a manner as possible. If the limb is suddenly pulled, or stretched by fits and starts, the muscles concerned in effecting and maintaining the displacement will inevitably be thrown into violent spasmodic contraction, thus not only causing pain, but, perhaps, severe injury to the soft structures, if not actually frustrating our intention. The degree of force used in making extension must vary according to the amount and character of the displacement, and the number and power of the muscles engaged in producing it; in all cases it should be sufficient to remove the shortening of the limb, or, what is the same thing, to restore it to its normal length, and to surmount every obstacle that opposes the reduction. The extension is always begun in the direction of the lower fragment, and is afterwards continued in that of the injured bone, until the object is fully attained. The ends of the fragments being now pressed into their natural situation, the fractured limb is immovably fixed by splints, every hollow between them and the skin being filled with cotton, to ward off pressure. Any spasmodic action of the muscles that may interfere with the reduction of a fractured bone is generally very readily counteracted by a few deep whiffs of chloroform; or, even without the aid of this agent, simply by the compression of the main artery of the limb, thereby lessening the flow of blood to the parts.

In fractures of the superior extremity, the hand and forearm are suspended in a sling,

and the patient may walk about and attend to business; but when the thigh or leg is involved, he must remain in bed until the ends of the broken pieces are completely consolidated, or until he has so far recovered that he can use the immovable dressing and exercise in the open air upon crutches. During his confinement, the limb is placed in the most favorable manner for relaxing and resting the muscles which pass over the fracture; for this purpose it should be put in the extended position, and be well secured with apparatus designed to maintain permanent extension and counterextension. In some cases the limb is placed in the semiflexed position, over a double inclined plane, but this will seldom be necessary or proper, except, perhaps, in fracture of the upper part of the body of the thigh-bone, attended with great and obstinate displacement of the superior fragment, in consequence of the joint action of the psoas and iliac muscles. In transverse fracture of the patella, the thigh and leg are sometimes placed over a single inclined plane, the foot being considerably elevated above the level of the trunk.

The treatment of fractures of the lower extremities is now very generally conducted in this country by extension with adhesive strips, weight and pulley, inasmuch as it is not only very simple but very effective. The limb is supported by appropriate splints, long and short, by the immovable bandage, or by sand-bags, as necessity or convenience may dictate. A short, narrow piece of wood is placed between the adhesive strips below the sole of the foot for the attachment of the cord connected with the pulley. The weight, composed of shot, iron, or other material, varies, on an average, from five to fifteen pounds, according to the age of the patient, the obliquity of the fracture, and the amount of muscular resistance. The necessary counterextension may readily be made by raising the foot of the bedstead. In paralysis of the limb but little weight will be required, and in no event should it be so great as to cause uneasiness or suffering.

When adhesive strips and the immovable apparatus are used, it will save the patient much suffering and the surgeon great trouble if the limb be well shaved previously to their application. Indeed, it is hardly possible to pay too much attention to every little detail tending to promote comfort and speedy recovery.

A fracture occurring in an ankylosed limb requires no special treatment beyond the adaptation of peculiar splints, to meet the exigencies of the particular case. A similar remark applies to fracture of the bones of the stump of an amputated limb, and to fracture of a limb which is the seat of an old, unreduced, or irreducible dislocation.

After-treatment.—The fracture having been reduced and dressed, the patient is carefully watched, in order that he may be safely conducted through his long and arduous confinement. His diet for the first few days should be light and cooling, and the bowels should not be disturbed for the better part of a week, unless it is absolutely necessary, in which event some mild aperient, as a dose of castor oil, Rochelle salt, or citrate of magnesium, may be administered. If fever supervene, antimonial and saline preparations are to be freely used, aided, if the symptoms are urgent, and the patient is plethoric, by venesection, and aconite or veratrum viride, although general bleeding will rarely be called for. Action having subsided, the patient gradually resumes his accustomed diet, being still careful, however, to err rather on the side of abstinence than on that of excess. Pain is relieved by anodynes; the bladder, if necessary, by the catheter.

During all this time the fractured limb is carefully watched, the patient being visited for a while at least once a day, or, if the case is at all troublesome, even twice a day, until all danger of mischief is over. If considerable pain and swelling exist, it will be well to remove the dressings at the expiration of the first twenty-four hours, otherwise they may be retained for a longer time. While I am an advocate for the careful supervision of the dressings. I am opposed to frequent change, as it tends to injure the ends of the broken bone, and to impede the reparative process. If the first dressings have been applied lightly, as they always should be, and the parts are well seen to afterwards, it is hardly possible for the patient to do badly. The great danger, in nearly all cases, so far as the safety of the limb is concerned, is during the first week; that passed, there is seldom any risk.

In most fractures of the long bones there is more or less spasm, jerking, or twitching of the limb, coming on within the first ten or twelve hours after the accident, much to the discomfort both of the part and system. This is owing partly to the pressure and irritation produced by the ends of the fragments, partly to the inflammation of the muscles, and is, in general, easily remedied by the rectification of the displacement, aided by warm applications and a full anodyne, either alone or in union with camphor and tartar emetic. Relief often follows in a peculiarly happy manner the hypodermic introduction of morphia. The worst forms of this complaint are met with in nervous, irritable persons, in whom it

occasionally persists with great obstinacy, despite our remedies, for a number of days, much to the annoyance of all concerned.

In fractures of the thigh and leg, especially the latter, the limb must be carefully protected from the pressure of the bedclothes, by means of a contrivance, such as that exhibited in fig. 426. It consists of two pieces of wood connected by several semicircles of hoop, or wire, attached by a longitudinal piece.

Fig. 426.

Wire Rack for Fracture of the Leg.

In fracture of the superior extremity, the patient is often able to walk about immediately after the accident, taking outdoor exercise, and, perhaps, even attending to business. But it is very different when he has a broken leg or thigh. Here, as a general rule, he is obliged to remain recumbent, often for a most unreasonable time, until, it may be, he is bedridden, and worn out with suffering. This is wrong. Such a case demands an immediate change of treatment. The starched bandage is substituted for the previous dressings, and the patient is sent out into the open air upon crutches. Prompt amendment follows; the general health rapidly improves, and the process of repair, having received a new impulse, steadily advances to completion.

As fractures are constantly liable to be followed by weakness and stiffness of the limb, the rule is to move the joint nearest the injury as soon as the union is sufficiently advanced to preclude the possibility of displacing the fragments or interrupting the consolidating process. This constitutes what is called passive motion, a most important element in the management of this class of lesions. It should not be commenced, as a general rule, before the end of the third week, after which it should be repeated once a day, or every other day, according to circumstances; it should be very gentle at first, and be gradually increased until the limb has completely regained its normal functions. During its performance the parts are properly supported by assistants, and the dressings are reapplied the moment it is over. The restoration of lost function will be greatly promoted by frequent ablutions with warm water and soap, followed by systematic massage and frictions with some sorbefacient lotion, as spirit of camphor, soap liniment, or weak solutions of iodine.

As soon as the callus has acquired sufficient firmness to sustain the ends of the broken bone, the splints and bandages are either discontinued, or applied more loosely, the object now being merely to keep the parts at rest until the union is perfectly consolidated. In fractures of the inferior extremity, some days should usually elapse before the patient is allowed to rise, and no weight should be thrown upon the affected limb under a fortnight or three weeks; the new bone is still weak, no definitive callus has yet formed, and the individual, awkward from long disuse of his joints, is liable to fall from the slightest accident. These precautions are so extremely important that they should always receive the most scrupulous attention.

Immovable Dressing.—The treatment of fractures by the immovable dressing is now almost universally employed in this and other countries, either alone or in union with other means. The plan is applicable to fractures not only of the extremities but also to those of the trunk, especially of the clavicle, scapula, ribs, and pelvis, and, if properly carried out, is a time-saving expedient, at the same time that it adds greatly to the patient's comfort and the ultimate success of the treatment. To Seutin, of Brussels, Velpeau, of Paris, and Dr. Van Buren, of New York, the profession is mainly indebted for the introduction of this valuable method of treatment. It is not, of course, applicable to all cases; but if proper care and judgment be exercised in their selection, there are few in which, in some stage or other of their progress, it may not be advantageously employed. There are many excellent surgeons, prominently among them Yandell and Cowling, of Kentucky, Erichsen and Croft, of England, and Von Langenbeck, of Germany, who are in the habit of applying this dressing, as a rule, immediately after the occurrence of the fracture, whether simple or complicated, and such a treatment has certainly its advantages, especially in hospital practice. But is it equally safe in private practice? In public institutions, where the surgeon is an autocrat in his wards, where he has complete control over his patients, and where the resident physicians and nurses exercise a constant surveillance, there can be no objection to such a procedure; for, if anything untoward arises, immediate relief is at hand. But it is widely different in private practice, especially when the patient and the professional attendant are at a considerable distance from each other; if, in such cases, the dressing is too tight, or improperly applied, great suffering, violent inflammation, or even gangrene may occur, before it can be removed and the evil remedied. For these reasons, I am myself averse to the early

use of the immovable apparatus, convinced that, as a rule, the safest plan is to wait until the resulting inflammation and swelling, of which, even in the more simple cases, there must generally be more or less, has completely subsided. From five to ten days, according to the amount of injury, should, on an average, in my opinion, be allowed to pass before a fractured extremity is put up in such a dressing; employed earlier, it may induce undue compression, and thus compel removal. I would, then, have an eye to time and circumstances; avoiding premature interference, on the one hand, and too long delay, on the other.

The immovable dressing may be prepared with various substances, all of them possessing more or less, although not equal, merit. Cowper, an old English surgeon, employed compresses and bandages, saturated with a mixture of the albumen of eggs and wheat flour, which was replaced by Lawrence by powdered chalk. Seutin was the first to recommend starch; Velpeau used dextrine; Smee prefers gum arabic and whiting; gum shellac and glue have their advocates; the plaster of Paris dressing has been justly lauded, and of late much has been said in commendation of paraffin, silicate of sodium, and silicate of potassium. All these various articles possess the advantage of cheapness, and of being easily prepared, applied, and removed, as well as being always easily procurable.

Of all these substances, the most valuable and reliable are plaster of Paris, silicate of sodium or potassium, and paraffin. The starch bandage has become obsolete; and dextrine is seldom, if ever, employed by the surgeons of this country.

Plaster of Paris was originally recommended as a scientific dressing in the treatment of fractures by Professor Kluge, of Berlin, in 1829, although it had been previously used for a similar purpose by Hendrikes, of Gröningen. The bandage is prepared by rubbing the dry plaster, of the finest quality, and freshly calcined, thoroughly into the meshes of a thick, coarse muslin or crinoline roller, which, if not required for immediate use, is loosely wound, and kept in a dry place until needed, when it is soaked for a few minutes in cold water. The limb, carefully enveloped in flannel, wadding, or old linen, is surrounded with the bandage in the usual manner, from three to four layers generally sufficing for the purpose. If, when the application is completed, the dressing is not firm enough, a mixture of plaster and cold water, of cream-like consistence, may be rubbed on with the fingers until the surface presents a smoothly polished appearance. Care, however, must be taken not to apply it too freely, otherwise it will make the dressing too brittle for comfort and usefulness. No splints need be employed, as any additional support that may be required may readily be supplied by folded cloths, saturated with the plaster, and stretched along the limb. It should be remembered that a solution of salt in warm water promotes the setting of the plaster, while the addition of a small quantity of glue or stale beer retards it. The great advantages of this dressing are, the rapidity with which it dries and adapts itself to the parts, and the fact that it forms an unusually firm, hard casing, which permits the limb to be handled and moved with great ease during any transportation that may be necessary to place the patient in more suitable quarters. A layer of varnish, applied the day after the dressing, will prevent the plaster from chipping.

It is very important that the plaster, in preparing the bandage, should be rubbed as thoroughly and equably as possible into its meshes. This can seldom be done with the hand. To meet this contingency, Dr. Marcy, of Boston, has devised an apparatus, represented in fig. 427, which distributes the powder uniformly upon both sides of the cloth by drawing it from below upwards through the dry plaster.

The *Bavarian dressing* for fractures, so extensively used during the Franco-German war, is an easy and effectual mode of applying plaster of Paris. When employed for frac-

Marcy's Plaster Bandage Roller. *a*, the part of the apparatus secured to the table *c*; *b*, the slide, which, when pushed down, holds the plaster on both sides of the bandage *d*, which is rolled up at *e*.

tures of the leg, two pieces of flannel, long enough to extend from the ham nearly to the toes, are stitched together behind, so that the seam shall correspond to the middle line as far as the heel, beyond which both layers are divided in the same line for adaptation to the foot. The sides of the layer next the skin are firmly sewed together in front of the limb and along the sole and instep, when the plaster is thickly spread over the entire casing, and covered by the outer layer of flannel, the flaps of which are then secured with stitches in front. When the plaster is set, the stitches are cut, the super-fluous edges of the splint are trimmed off, and the apparatus is secured by a bandage or by tapes passed through eyelets. The seam behind serves as a hinge, through which the dressing may be removed and readjusted with the utmost facility. In fig. 428, from Bryant, the limb is seen to be supported by a bandage carried through the superfluous edges of the flannel, for greater convenience of application.

Fig. 428.

Bavarian Splint. a, first layer of flannel applied to the limb; b, second layer about to be applied.

The *silicate of sodium* or potassium in saturated solution, applied with a stout brush, constitutes what is called the glass dressing, as it forms, when well rubbed into the meshes of a wet roller, a firm, immovable apparatus, in no wise inferior to that of plaster of Paris. Indeed, in certain situations, as in fractures of the clavicle, scapula, and ribs, it deserves a decided preference. The glass dressing dries very rapidly, does not irritate the skin, is easily procured, and is, withal, very cheap. The under dressing is the same as in the plaster dressing. From three to five layers of bandage are, on an average, necessary to impart the requisite amount of stiffness; and occasionally the surgeon is compelled to interpose a binder's board, or some other thin substance, to afford additional support.

An excellent fracture dressing may be made of *paraffin*. After being thoroughly melted, this substance is partially cooled, to render it more viscid, when it is rubbed freely into the meshes of the bandage with a coarse paint-brush, forming thus a very neat, light dressing, perfectly impermeable to water, pus, and other fluids, and, therefore, admirably adapted to the treatment of compound fractures, and also to simple fractures in young children, in whom the ordinary contrivances soon become soiled with the natural excretions.

The *glue dressing*, also a very excellent one, is prepared by rubbing into the bandage warm glue, diluted immediately before it is used with a fifth part of its bulk of alcohol or a small quantity of oxide of zinc, to promote desiccation. The mixture, applied in the usual manner, soon begins to harden, although it does not become perfectly dry under several hours. From two to four layers of bandage, with one of wadding next to the limb, usually suffice. If additional strength be required, fresh strips of linen may be glued on without changing the original dressing, which generally retains its place until the fracture is consolidated.

The apparatus of Smee, known as the *moulding tablet*, forms a very good dressing, nowise inferior to the stiff bandage, and but little, if any, more expensive. It consists of two layers of coarse, old sheeting, cemented together by means of a thick paste made by rubbing very finely powdered whiting with mucilage of gum arabic. The sheeting soon dries, without shrinking, into a hard, firm substance, which, with the aid of a sponge and hot water, may afterwards be accurately moulded to the fractured limb, and worn with great comfort and efficiency.

Tripolith was suggested, in 1880, by Von Langenbeck, as a substitute for plaster of Paris in the treatment of fractures, on the ground of its making a lighter dressing, and one that would dry more rapidly, from three to five minutes generally sufficing to render it perfectly solid. It has been asserted that it does not readily absorb moisture, and that it undergoes no change from contact with water; a statement which, however, is not strictly correct. Dr. Samuel N. Nelson, of Boston, who has made some trials with it, considers it utterly untrustworthy. The dressing is prepared and used in the same manner as the plaster dressing. Tripolith consists mainly of calcium and silicium with a small quantity of protoxide of iron.

The *egg paste*, as it is termed, makes, if properly used, a very firm dressing, admirably adapted to cases requiring the immovable apparatus. It is prepared by mixing the white of eggs with a sufficient quantity of flour, until it assumes the consistence of a thick solu-

tion of gum arabic, when it is rubbed into the meshes of the roller previously wrung out of water. When dry, the bandage forms a firm, hard case.

Whatever immovable dressing be used, it is indispensably necessary to keep up extension and counterextension by assistants, or other suitable means, until the apparatus is sufficiently solidified to prevent displacement of the fragments. In some cases, as when there is inordinate tendency to displacement, the extension and counterextension may be obliged to be continued for a considerable length of time, if, indeed, not permanently, or until the process of reunion is completed.

When the dressing, of whatever material it is composed, is perfectly dry, it forms an immovable case for the limb, making equable and uniform pressure throughout, and maintaining the fragments of the broken bone accurately in apposition. If the parts feel entirely comfortable, the patient may now sit up in bed or on a chair, or he may even walk about on crutches, the leg being properly supported in a sling. Generally, however, it will be found that there is for a day or two a sense of soreness, with, perhaps, some degree of throbbing, inviting recumbency rather than the erect post-

Fig. 429.

Seutin's Scissors.

ure. If the apparatus causes marked discomfort, by bearing unequally upon any portion of the limb, or if throbbing and swelling arise, it must immediately be removed. For this purpose it should be slit up with Seutin's scissors, represented in fig. 429, or with a shoemaker's knife, or a Hey's saw, the tract to be cut in the dressing being previously softened with hot water applied with a sponge. The limb being properly supported by an assistant, the hardened shell is gently peeled off from its surface, which is then carefully sponged with alcohol and laudanum, or spirit of camphor, when the apparatus

Fracture of the Thigh, done up in Immovable Dressing.
Dressing in Compound Fracture of the Leg.

is immediately reapplied with the aid of a roller; or, instead of this, eyelet holes may be inserted, at suitable distances, in the border of the dressing, and retention effected with pieces of narrow tape. Thus, by simply opening the dressing from time to time, an opportunity is afforded of inspecting the limb, and ascertaining its precise condition, not only at the seat of fracture, but everywhere else. When the patient is able to move about

on crutches, the limb should be carefully supported in a sling, arranged in the manner represented in fig. 430.

When the fracture is seated high up in a limb, the apparatus should extend a short distance above it, as it is a matter of great moment to keep the joint in as passive a condition as possible. In compound fracture, attended with discharge, a hole should be cut in the apparatus opposite the wound, so as to admit of the necessary drainage, as shown in fig. 431.

Great care should be taken that the edges of the splints do not produce any injurious compression; to obviate this, it is usually recommended that they should be torn instead of being cut, it being alleged that, when thus treated, they will be much less likely to create mischief. My experience, however, is that this is not the fact, and I, therefore, invariably bevel the inner edges with a stout knife, thereby effectually preventing all risk of this kind.

It is impossible, also, to bestow too much attention upon the bandage; the care or negligence with which this is applied will make all the difference in the result, both as it respects the patient's comfort and the character of the cure.

Shortening of the Limbs after Fractures.—I think I am not wrong when I assert that more or less shortening of the limb in fractures of the lower extremity is almost universal, no matter how carefully, or in what manner, the treatment may be conducted. This remark, however, applies solely to oblique fractures, and has no relevancy whatever to transverse fractures which, as a rule, if not in every case, if properly managed, ought to get well without any deformity whatever of this kind. The amount of shortening will vary, of course, with the particular circumstances of each case, as the degree of obliquity of the fracture, the nature of the treatment, and, above all, the coöperation of the patient, on an average from the eighth of an inch to half an inch. In many cases it will necessarily exceed half an inch, and it may even reach twice that extent without in the slightest degree impairing the usefulness of the affected limb, unless it should naturally be considerably shorter than the sound one. In exceptional cases there may be an entire absence of shortening; and it should be borne in mind that in hospital practice, where the patient is always more fully under the control of the surgeon, and where the means and appliances for treatment are better adapted to the object, there is less excuse for the occurrence of shortening and deformity than in private practice, where the reverse is so often the case. The treatment of fractures of the humerus, however carefully conducted, is very liable to be followed by more or less shortening; in fractures of the shafts of the bones of the forearm shortening is uncommon.

Shortening in fractures of the bones of the lower extremity is often due to the premature removal of the extending apparatus and to the too early use of the limb. The weight of the body being thus thrown upon the broken bone, before the callus is sufficiently hardened, forces the ends of the fragments apart, and thereby occasions not only shortening but more or less lateral deformity; in fact, the connecting material may, in this way, even be completely destroyed.

The subject of the symmetry in the length of the extremities, upper as well as lower, is one that intimately connects itself with the present inquiry, and is of great interest not only in its practical bearings but also in a medico-legal point of view, as cases attended with marked shortening of the limb after the cure of fractures are not unfrequently carried into court for the recovery of damages, on the ground of alleged malpractice. Fortunately, thanks to the labors of a number of recent zealous investigators, this matter is now fully settled, and while I cannot agree with some of them, as for example, Dr. William Hunt, of this city, who has greatly interested himself in the study of this subject, and thrown valuable light upon it, that asymmetry of the limbs exists as a rule, I am prepared to affirm that it is present in very many, if not indeed, in a majority, of cases. The attempts to solve this question were begun at the Pennsylvania Hospital, in 1875, at the instance of Dr. Thomas G. Morton, by Dr. William C. Cox, one of the resident physicians, who found, in 54 cases, the right lower limb the longer in 23, and the left in 25, 6 presenting no difference. In the 48 cases the variations ranged from $\frac{1}{8}$ to $\frac{3}{4}$ of an inch. It is proper to observe that these observations were made with a tape extended from the anterior superior spinous process of the ilium to the internal malleolus, while the subject lay flat upon his back, upon a hard surface. Similar results were obtained two years later by Dr. J. S. Wright, of Brooklyn. Finally, in 1879, as if to remove all doubt upon the subject, Dr. Morton, in an examination of 513 boys from eight to eighteen years of age, found inequality in the lower limbs in 272, while in 241 there was no appreciable difference. In 91 the difference was $\frac{1}{8}$ of an inch; in 100, $\frac{1}{4}$; in 41, $\frac{3}{8}$; in 22, $\frac{1}{2}$; in 12, $\frac{5}{8}$; in 2, $\frac{3}{4}$; in 2, $1\frac{1}{8}$;

and in 1, 1⅜. Of the 272 cases of inequality the right limb was the longer in 198, and the left in 74.

These measurements tally well with similar ones made on the skeleton. Thus, in eight examinations made by Dr. John B. Roberts, of this city, the difference in the length of the lower extremities ranged from one-eight to three-eighths of an inch; the tape being extended from the top of the femur to the internal malleolus. Dr. J. G. Garson, in 1879, examined the thigh-bone and tibia of 70 skeletons of various ages and races in the museum of the Royal College of Surgeons of London, in only twenty per cent. of which the extremities were of equal length. The left leg was the longer in 38 cases, and the right in 25. The left femur in 46 cases, and the right in 20. It is worthy of note that in advanced life, and especially in persons who have suffered severely from chronic arthritic disease of the hip-joint, there is often, as all anatomists and surgeons know, great diminution in the length of the thigh-bone, from interstitial absorption of its head and neck, attended with great alteration in their form and direction. In this manner, shortening, often amounting to upwards of an inch, may readily be induced, as I know from the inspection of numerous specimens, and as I have long taught in my lectures.

Various contrivances for accurately determining any irregularities that may exist in the length of the lower extremities in health and after injuries have been devised by different surgeons, among others by Dr. T. G. Morton, and Dr. B. E. Gibbs, the former of whose paper on the subject, accompanied by a graphic illustration, may be found in the American Journal of the Medical Sciences for January, 1877.

3. COMPLICATED FRACTURES.

The only class of fractures, besides the simple, which deserves to be considered under a distinct head, is the complicated, as it is easy to comprise under this denomination every form of accident that can possibly arise either at the moment of the injury, or during the progress of the treatment. The most important topics requiring attention are wounds, hemorrhage, dislocation, comminution of bone, excessive laceration of the soft parts, erysipelas, pyemia, and, lastly, tetanus.

Complicated fractures may be oblique, transverse, or longitudinal, the frequency of their occurrence being in the order here enumerated. They are always caused by mechanical violence, as gunshot, falls from a great height, severe blows, or the passage of the wheel of a carriage, wagon, or railway car. Complicated fractures from the latter cause are very common, and are a frequent source of loss of limb and life.

The symptoms of this variety of fracture are, like those of simple fracture, sometimes extremely obscure, requiring great care and skill on the part of the surgeon to determine their character. In general, however, they are sufficiently well marked to enable him to distinguish them from such as attend other accidents, especially if the parts can be thoroughly examined before the supervention of much swelling. There are usually greater pain and shock than in an ordinary fracture, the resulting inflammation is more severe, and there is greater risk of violent secondary effects, as erysipelas, gangrene, copious suppuration, necrosis, caries, prostration, hectic irritation, and tetanus. In fact, complicated fractures are among the most serious occurrences that are met with in practice, being alike perplexing to the surgeon and dangerous to the patient; demanding the nicest judgment and skill for their successful management, and entailing, not unfrequently, the greatest possible suffering, horrible deformity, and loss of limb, if not also of life. It may be stated, as a general rule, that complicated fractures of the lower extremity are more dangerous and difficult of management, as well as more liable to be followed by distortion and permanent lameness, than those of the superior.

The process of repair in complicated fracture proceeds on the same principle as in the simple form of the lesion, only that it is usually more tedious, and that it is attended with a larger quantity of callus. When there is a wound in the soft parts, the union is generally effected through the medium of granulations, which, arising from the medulla of the Haversian canals and the central canal, are directly converted into osseous tissue, and thus form the connecting link between them.

The *treatment* of this form of fracture varies according to the circumstances of the case, or the nature and severity of the complication. When the case is associated with a wound in the soft parts, constituting what is called a *compound fracture*, as in fig. 432, and the limb is deemed capable of preservation, the first and most important consideration is the reduction of the fracture. This may generally be done by putting the limb in the most favorable position for relaxing its muscles, and by well-directed and gentle efforts at

extension and counterextension, along with proper manipulation, especially if the fracture is transverse, and the opening large; but if it is oblique, and there is a projection of one or both ends of the fragments, they occasionally fail, and compel us to resort to other measures. Under such circumstances, the soft parts which gird or bind the bone, and prevent it from yielding, should be carefully divided, when a renewed attempt at

Fig. 432.
Fracture of the Leg complicated with Wound and Comminution of the Bone.

reduction will probably be successful. Should every reasonable effort of the kind, however, prove fruitless, then, instead of leaving the bone in its exposed situation, where it would be sure to die, the proper plan would be to cut away a portion of it, especially if it terminate in a very long and narrow point, care being taken to retain as much as possible of the periosteum.

Whatever may be the character of the wound, its edges should be carefully approximated by suture and plaster, aided by collodion to exclude the air; or, instead of this, the wound may be covered with a light compress wet with carbolized oil, and supported by a bandage. In this way, a compound fracture may occasionally be speedily converted into a simple one, union sometimes occurring in a few days. To facilitate cleanliness and the application of the dressings a bracketed splint must be used, one of the best of which is that of Dr. Packard, described in a future page.

Mr. Lister, in compound fractures, always injects the wound very thoroughly, as a preliminary measure, with a solution of carbolic acid, in the proportion of one part to twenty of water, the object being the prevention of suppuration by destroying the germs which, he alleges, constantly float about in the air, and which, if permitted to enter the wound, invariably interfere more or less with the reparative process. After the wound has been well cleaned and all fluid removed, the edges are adjusted in the usual manner, the surface is covered with a piece of protective antiseptic gauze, and the part is surrounded with lac plaster. The subsequent management is conducted upon general principles, the dressing being renewed as often as may be necessary, on account of the discharges, under a spray of a weak solution of carbolic acid continually playing upon the part, to prevent the ingress of air and of germs.

Whether carbolic acid, apart from the other means, recommended by Mr. Lister, is really of any benefit in the treatment of these injuries is still a mooted question. The rapidity with which wounds placed in the condition of subcutaneous wounds by the exclusion of the air heal, has long been familiar to surgeons. In India oil is extensively used for this purpose; and I have myself for many years employed this substance as a favorite dressing in all wounds made with the knife, as well as in fresh accidental ones. Sir Astley Cooper was in the habit of treating all compound fractures and dislocations with pledgets wet with the patient's blood, and confined by means of the bandage. Mr. Bennion, a Shropshire surgeon, enjoyed, as we are told by Mr. Adams, of London, great reputation for his successful treatment of compound fractures, accidents of frequent occurrence in his district, based upon similar principles. His method was, first, to effect thorough reduction of the ends of the fragments, even, if necessary, at the risk of great force; secondly, to clear away all effused blood; thirdly, to approximate carefully the edges of the wound; fourthly to cover the parts with a large pledget of lint, saturated with compound tincture of benzoin; fifthly, to bandage the entire limb, and support it with a well-fitting splint; sixthly, to put the patient at once under the influence of opium, maintained for a considerable length of time; and, lastly, to retain the dressings so long

as they did not cause any serious disturbance, evidently on the principle that meddlesome surgery is bad surgery.

A modification of the Lister treatment was introduced a few years ago into the New York Hospital by Professor Markoe, and has given most flattering results, only one death having occurred in nearly two hundred cases. The method consists in passing a large drainage-tube through a counter opening at the seat of the injury, in putting up the limb in plaster dressing provided with suitable fenestra, and in injecting a stream of carbolized water through the drainage-tube, at first every two hours and afterwards regularly three times a day until a cure is effected. No change of dressing is required; the thermometer rarely rises above 102° Fahr.; and the danger of erysipelas and pyemia is vastly lessened.

The opium treatment in these accidents cannot be too strongly commended. Much of the mischief caused by them is doubtless due to the neglect of its employment. Given in liberal doses, opium not only allays pain but prevents spasm and tranquillizes the system, all important elements of treatment in such cases. The wound should be most thoroughly closed by suture, proper provision being made for drainage, especially if the parts be much bruised or lacerated; and covered with lint wet with blood, benzoin, collodion, or Richardson's styptic colloid, supported by an oiled compress and a roller, extending from the distal portion of the limb.

The *hemorrhage* in complicated fracture may be open or concealed, according as there is a wound or no wound; arterial or venous; insignificant or copious. In the first case, the bleeding will manifest itself in the usual manner, and is to be arrested by ligature, acupressure, or compression; in the second, it will be indicated, if it is at all considerable, by unusual swelling, attended with a sense of fluctuation or unusual softness, and by more or less discoloration of the integument. If the principal artery of a limb has been severed, there will be an absence of pulsation in the parts below, with coldness of the surface. When no doubt remains concerning the diagnosis in such a case, the main trunk of the vessel is exposed some distance above the seat of fracture, and ligated; or, if this be deemed improper, an incision is made through the bloody tumor, and, its contents being turned out, the divided artery is sought and secured above and below the seat of injury. This, in fact, is usually the preferable procedure, especially as there must frequently be considerable uncertainty whether the effusion is arterial or venous; a circumstance which, perhaps, thus leads to the performance of a most serious operation in a case where one of a most simple character might suffice.

The formation of a distinct *aneurismal* tumor is very uncommon in injuries of this kind. The occurrence is denoted by pulsation, by thrill, and by a sawing, rasping, or purring noise, by circumscribed enlargement, and by the other usual concomitants. If the disease do not disappear spontaneously, as occasionally it does, an attempt must be made to effect a cure by compression, either digital or mechanical; or, if this fail, by ligation of the affected artery.

When a fracture is attended with a *dislocation*, the case necessarily assumes a very serious character, as it may give rise, especially if the joint involved is a large one, or the bone greatly shattered, to the question of primary amputation. In such an event the most experienced surgeon will often find it difficult to come to a prompt and correct decision. The principal circumstances which should induce him to make an attempt to save the limb are, the integrity of the patient's health at the time of the injury, together with a knowledge of his previous habits, and the simplicity of the dislocation, or the almost total absence of complication, as it respects the affected joint. If, on the other hand, the dislocation is compound, and the bone is badly broken, at the same time, perhaps, that it protrudes at the articulation; if all these injuries exist; or if, along with them, serious mischief has been inflicted upon the soft parts, as a violent contusion of the skin and muscles, or the laceration of important vessels or nerves, no doubt should be entertained respecting the propriety of the operation, and the sooner it is performed after the occurrence of reaction the better it will be for all parties concerned. I believe that a compound fracture, extending into a large joint, as the knee or ankle, and attended with extensive rupture of the ligaments, muscles, and other structures, should always, as a general rule, be treated in this way. It is true, a case apparently of the most desperate character occasionally recovers, but such a consideration should not have too much weight, or induce us to neglect a measure which is sanctioned not less by reason than by experience.

When the case is such as not to demand amputation, the dislocation should be reduced before an attempt is made to adjust the fracture. For this purpose the limb at the seat of the injury should be rendered as firm and immovable as possible by splints and bandages,

and the efforts persisted in until the object is attained. To wait until the broken bone has become sufficiently consolidated to enable it to bear the requisite manipulation would be sheer folly; one of two things would almost inevitably happen in such a case, either a reproduction of the fracture, or an utter failure to replace the luxated bone.

The most common causes of *comminuted* fracture are, gunshot violence, railway accidents, falls from a great height, and the passage of the wheel of a carriage. If the bone is splintered and any of the pieces are completely detached, or so loose as to render their reunion improbable, they must be carefully removed, the edges of the wound being afterwards gently approximated, and kept in position by sutures and adhesive strips, covered with collodion. The limb, surrounded by the bandage of Scultetus, and supported by appropriate apparatus, is placed in an easy position, and care is taken to moderate inflammation by the usual antiphlogistic means. If the wound suppurate, the best application will be an emollient poultice or the warm water-dressing, with as little disturbance as possible to the injured bone.

The so-called simple fracture, that is, a fracture without wound, is sometimes attended with a shattered and comminuted condition of the bones, imperilling limb and life, and imperatively demanding amputation. When there are only three or four fragments, and they admit of accurate adjustment, such an operation is of course not to be thought of, ordinary measures generally sufficing for a good cure.

A simple fracture becomes occasionally a complicated fracture from the manner in which the ends of the fragments pierce the muscles, thereby, although the fracture may be strictly subcutaneous, rendering it impossible to restore them to their proper relations. In such a case the only thing to be done, after failure of the ordinary means, is to cut through the skin and liberate the fragments with the bistoury, a procedure not likely to alter materially the risk of the case.

A fracture complicated with *impaction* of the ends of the fragments is occasionally a source of great annoyance to the surgeon. The most common sites of such a fracture are the head of the humerus, the lower extremity of the radius, and the neck of the femur. In most cases it will be good practice not to disturb the parts, but let them unite in their new position, as their separation is liable to be followed by want of union and other bad consequences.

When the fracture is complicated with violent *contusion* of the soft structures, the retentive apparatus should be applied rather slackly, and the parts kept constantly wet with cold water, or, what is better, a strong solution of acetate of lead and opium. If the inflammation run high, and the patient is strong and vigorous, bleeding, purgatives, and antimonial preparations may become necessary. The limb is carefully watched, in order that prompt advantage may be taken of any changes that may arise.

In gunshot fractures of the bones of the lower extremities attended with great displacement, Dr. Benjamin Howard, of New York, has on several occasions cut down upon the bone, and connected the ends of the fragments with silver wire. How far such a procedure may be judicious or proper, future experience alone can determine. When the tendency to displacement is very great, or cannot be controlled by the ordinary measures, I should think well of it; but few such cases will be likely to occur under the present improved system of treatment.

In consequence of injury sustained by the skin, either at the time of the accident, or from the pressure of the bandage, the cuticle is sometimes raised into little *vesicles*, filled with a thin, limpid, reddish, or yellow fluid. Such an occurrence always awakens anxiety both in the patient and practitioner, especially if he is young and inexperienced, as it is apt to be associated with the idea of gangrene. From this, however, it may always be easily distinguished by the absence of lividity, severe pain, and other symptoms of excessive action. The proper treatment consists in puncturing the vesicles with a fine needle, and dusting the surface with powdered zinc, unless the part is hot and inflamed, when water-dressing, simple or medicated, should be used.

If the principal artery, vein, or nerve of a limb has been destroyed, at the same time that there is extensive laceration of the soft parts around, the case will probably require amputation, especially if there has been severe shock or extensive hemorrhage, with previous derangement of the general health. Such a case is, at all events, a bad one, liable to be followed by loss of limb, if not also of life. If, on the other hand, the principal artery retains its integrity in the midst of the torn and broken structures, and the patient is young and vigorous, although he may have bled severely, we should by all means make an attempt to save the limb, having previously explained to the patient and his friends the risk which such an undertaking involves. Some of the most gratifying results that

reward the care and skill of the practitioner are cases of fracture complicated with extensive laceration of the soft structures and comminution of the bones. I have several times succeeded in effecting excellent cures when, the main artery being intact, the limb hung merely by a comparatively small quantity of skin and muscle, and when I was compelled to remove a number of pieces of bone, or even saw off the ends of the fragments.

A fracture complicated with *ankylosis* of a neighboring joint, or occurring in the bones of a stump, must be managed upon the same principles as an ordinary fracture, the apparatus being modified to meet the peculiar contingencies of the case. A fracture occurring in a paralyzed limb generally unites in the ordinary time, provided care be taken not to make undue compression during the after-treatment, lest it interfere with the nutrition of the bone and the formation of callus.

Accidents after Complicated Fractures.—The most common and important accidents after complicated fracture are spasm, erysipelas, œdema, abscess, gangrene, tetanus, pyemia, delirium, and congestion of the brain and lungs.

Spasm of the muscles is sufficiently common after all fractures of the limbs, but is especially liable to occur after fractures complicated with severe luxation of the soft structures and injury to the nerves from the contact of the sharp ends of the fragments. It is generally most severe and troublesome during the first two or three days, and always requires the liberal use of anodynes for its relief. The best local remedy is hot water medicated with acetate of lead and laudanum.

Erysipelas is very common after complicated fractures, and usually comes on within the first forty-eight hours after the receipt of the injury, manifesting itself in discoloration of the skin, more or less tumefaction and burning pain. The disease is most liable to appear in persons of intemperate habits, and in such as are dyspeptic, or enfeebled by previous suffering, and generally adds very much to the danger of the case, perhaps already sufficiently grave. Its extent and continuance will depend upon various circumstances, which will readily suggest themselves to the mind of the reader. The treatment is conducted upon general principles, the main reliance being upon the correction of the secretions, and the support of the system by fresh air, quinine, iron, milk punch, nutritious food, and anodynes, with the topical application of dilute tincture of iodine. Scarifications and incisions are not omitted in the event of great tension, or tension and suppuration.

The occurrence of *œdema* is sufficiently frequent in complicated fractures of old, dilapidated subjects, and is best remedied by the bandage, aided by spirituous lotions, tonics, and a nutritious diet. Punctures will seldom be necessary, and should always be employed with the greatest caution, as they are liable to be followed by bad sores and even gangrene.

Abscesses, diffuse, painful, and troublesome, may form at the seat of the fracture, or in its immediate vicinity. In either case, the matter should be speedily evacuated and thorough drainage established: otherwise it may not only cause extensive havoc among the soft parts, but caries and necrosis of the ends of the broken bone, with risk of pyemia and phlebitis.

Gangrene may be produced by injudicious bandaging obstructing the circulation, excessive inflammation, or injury of the main artery, vein, or nerve of the affected limb. The occurrence is most common in unhealthy subjects and in young persons after railway and other severe accidents, and often makes fatal progress before its presence is suspected by the patient or his attendant. Great pain in the part, of a smarting, pungent, or burning character, accompanied by discoloration and tumefaction in the distal portion of the limb, should always excite alarm and lead to a thorough examination. Tight bandaging, in particular, should be avoided in complicated fractures, especially in the early stages of the treatment.

Gangrene in complicated fractures is sometimes produced by excessive compression of the soft parts by extravasated blood, poured out in such quantity as to arrest the circulation in the principal vessels of the limb. Such an occurrence will be still more likely to take place when an important artery, vein, or nerve has been seriously wounded. The treatment must be by free incision and evacuation of the clotted blood, along with ligation of any wounded vessels above and below the seat of the injury. Amputation may be required if mortification has taken place.

Mere embolism may possibly give rise to gangrene below the seat of fracture, the blood coagulating in the principal vessels from the effects of inflammation independently of any pressure by the ends of the fragments. Such an event would be most liable to occur in a comminuted fracture, attended with great contusion and laceration of the soft structures, partially devitalizing the blood.

Secondary hemorrhage is an occasional occurrence in accidents of this kind, caused either by injury of an artery at the time of the fracture, or by the pressure of a fragment of displaced bone, producing ulceration in the coats of the vessel. In a case observed by Pelletan, the pressure exerted by a displaced piece of bone upon the anterior tibial artery caused profuse hemorrhage upwards of two months after the receipt of the injury, necessitating amputation. The management of such an occurrence must be conducted upon ordinary principles.

Necrosis of the ends of the fragments is not uncommon in compound fractures, especially if they have been stripped of periosteum, or long exposed to the air. The occurrence is denoted by the whitish and denuded appearance of the bone, the unhealthy condition of the granulations in the soft parts around, and the thin, watery nature of the discharges. In effecting retrenchment of the dead bone, whether with the hand or pliers, the same care must be taken to guard against hemorrhage, shock, and contusion of the osseous tissue. I have known a very slight loss of blood to be promptly followed by excessive exhaustion, placing the patient's life in jeopardy.

Severe *spasm* frequently attends this class of injuries, but as this subject has already been discussed in connection with simple fractures, nothing further need here be said respecting it.

Complicated fractures, especially if attended with loss of substance, are occasionally followed by the formation of a *false joint*, despite the best directed efforts of the surgeon. When the loss of bony matter is considerable hardly anything else is to be expected.

Chorea of a limb, whether existing previously to, or supervening after, the occurrence of the fracture, constitutes a very grave complication, seriously interfering with the success of the treatment. Chalybeate tonics, bromide of potassium, and anodynes, along with a properly regulated diet, afford the best chance of relief. In a case of fracture of the humerus, complicated with chorea, in charge of Dr. William Hunt, of this city, the patient died on the tenth day from the effects of the uncontrollable spasms of the limb.

Pyemia, as an effect of complicated fractures, is uncommon, at least in private practice, except when the accident has been caused by railway injury, the bursting of a gun, the passage of the wheel of a wagon, or some similar violence. It is distinguished by its usual insidious character, and generally sets in from the fifth to the tenth day, its approaches being announced by violent rigors, alternating with flushes of heat, great depression of the system, delirium, and excessive restlessness. The structures which are most apt to suffer are the lungs, liver, spleen, joints, and connective tissue. The treatment is supportant and alterant; by quinine, iron, brandy, and nourishing broths, for the former; by the sulphites of sodium and potassium, in moderately large and properly sustained doses, for the latter. In general, such cases fare badly, death occurring within a week from the commencement of the attack, despite our best directed efforts.

Tetanus, in complicated fractures, is most liable to supervene in nervous, irritable subjects, during hot weather, although it may take place at any season of the year, as well as in every description of individuals. It is an extremely formidable symptom, which should be promptly met by the removal of the affected parts, and by large quantities of anodyne and antispasmodic remedies. If occasionally a case is cured without amputation, it forms the exception, not the rule. In such an event, there is no time for delay; whatever is done must be done quickly and effectively, at the very inception of the disease, before there is any decided evidence of stiffness in the muscles of the jaw.

Traumatic *delirium* is sufficiently frequent after these accidents, especially in old intemperate persons, and should be treated upon the principles laid down in a previous chapter, the most important remedies being bromide of potassium, chloral, aconite, and opium.

Congestion of the *lungs* and other internal organs, as a consequence of these injuries, is most liable to occur in elderly persons, as a result of a determination of blood either from actual irritation or a sluggish condition of the vessels during protracted confinement. As such attacks are very liable to prove disastrous, everything should be done to prevent them, by getting the patient as speedily as possible out upon crutches into the open air.

Fatty embolism of the lungs and other viscera, caused by oil globules introduced into their substance by the veins at the seat of the fracture taking up some of the crushed marrow, and carrying it to these organs, where it causes fatal obstruction, is an occasional occurrence after such a lesion. The possibility of such an occurrence was first enunciated in 1862 by Zenker and Wagner, but it remained for Busch and Czerny to establish the fact by actual dissection. In the case reported by Czerny, the patient, a stout, healthy man, thirty-two years old, had a simple fracture of the thigh-bone, which was followed soon after the accident by symptoms of pulmonary obstruction, terminating in death in less than forty hours.

The post-mortem examination revealed the existence of great numbers of oil globules in the capillaries and smaller arteries of the lungs, brain, liver, and kidneys. Observations made by Bergmann, Déjérine, Hamilton, Busch, and others show that, while this form of embolism is most common after fractures, it may also take place in caries, in osteomyelitis, in bony tumors, in fatty degeneration of the liver and arteries, and in certain abscesses developed in regions abounding in adipose tissue.

Fractures of the *joints* are frequently complicated with sprains, laceration of the ligaments, detachment of portions of bone and cartilage, and extravasation of blood. The inflammation consequent upon such injuries often runs very high, large quantities of synovial fluid are liable to be effused, and the swelling in the surrounding structures is frequently very extensive. A severe sprain always adds greatly to the suffering, increasing the pain, and delaying recovery. In many cases the nutrition of the limb is seriously impaired, the muscles become atrophied, the skin is cold and discolored, motion is impeded, and the general health is more or less deranged. Extensive laceration of the ligaments is frequently followed by permanent ankylosis, or by such an amount of disorganization of the proper structures of the joints as to lead to the necessity of resection or amputation. When the articular extremity of a bone is severely shattered, a small fragment is sometimes completely detached, and, falling into the joint, sets up violent, if not destructive, inflammation. A piece of cartilage, however minute, may occasion similar effects. Abscesses, either circumscribed or diffused, are liable to form as a consequence of such injuries, sometimes at a period quite remote from their occurrence. More or less extensive extravasation of blood generally takes place in fractures of the joints, both into their interior and into the surrounding connective tissue, not only obscuring the diagnosis, but seriously impeding the cure. Permanent ankylosis occasionally follows upon a complicated fracture, even when situated at a considerable distance from a joint, simply from an extension of the resulting inflammation.

The *nerves*, like the bloodvessels, often suffer severely in fractures, sometimes at the moment of the injury, from contusion, laceration, or compression by sharp or displaced pieces of bone, or more or less remotely from the manner in which they are constricted by the plasma that is effused around their trunks at the seat of the original mischief. Exuberant callus may occasion similar effects, as I have witnessed in several cases. Whatever the cause may be, the suffering generally manifests itself in pain, more or less severe, and often of a neuralgic character, a sense of numbness, coldness or tingling, gradual wasting of the muscles, great susceptibility to atmospheric impressions, dryness and roughness of the skin, superficial ulcerations, the formation of little vesicles, desquamation of the cuticle, partial paralysis, and a tendency to ankylosis of the joints near the seat of injury. Some of these affections are remediable, yielding gradually to sorbefacient lotions, the hot and cold douches, and veratria ointment; others, on the contrary, obstinately persist despite the best directed efforts of the surgeon. Now and then relief, prompt and permanent, follows excision of a portion of the affected nerve.

The *muscles* and tendons passing along the seat of fracture often sustain serious injury, in the first instance from the displaced extremities of the fragments, fretting and irritating their fibres; and, at a later period, from their involvement in the callus, which, when this substance is unusually abundant, surrounds and compresses them in such a manner as to interfere permanently with the exercise of their functions.

As a remote effect of a fracture, even of the most simple kind, there is occasionally a development of sarcoma at the seat of injury, coming on within a variable period after its occurrence, and characterized by rapid formation and great bulk. In a case recently under my observation, an immense tumor of this kind existed in the forearm, in a boy, eight years old, who, twelve months previously, met with a fracture of the ulna. Latterly the lymphatic glands of the corresponding axilla had become involved, and the general health showed marked evidence of impairment. A section of the tumor exhibited, under the miscroscope, a typical round-celled structure.

Amputation.—The circumstances which are likely to call for primary amputation have already been casually alluded to, and it may now be added that the operation should always be performed, as a general rule, whenever, along with a shattered or comminuted condition of the fractured bone, there is extensive laceration of the soft parts, with almost total disorganization of their substance. It is true, as was before intimated, that apparently desperate cases are sometimes cured, and that limbs, so mashed and wounded as to render amputation the only probable chance of success, are now and then saved. But it is equally true that such instances are extremely rare, and if we take into account the protracted sufferings of the patient, and the likelihood that he will ultimately perish, the

reasons for performing immediate amputation are, to use the language of Percivall Pott, "vindicable upon every principle of humanity or chirurgic knowledge."

It is not uncommon to meet with cases in which the fracture is *multiple*, or in which the bone is broken at several points, but the upper fracture is perfectly simple, and perhaps situated in a portion of the limb which it is desirable to preserve. Hence it becomes an important question how the surgeon should act in such an event. To my mind, the subject is a very plain one. If it is really important to save the broken bone beyond the part that must necessarily come off, in order to make a longer and better stump, there can certainly be no objection to such a course, provided, however, that the proximal fracture is perfectly simple in itself, and that there is no serious lesion of the soft structures, endangering limb and life by gangrene or other bad consequences. I have more than once adopted this plan, without ever having had any cause to regret it. No sensible surgeon would, of course, allow a bone to remain, if, in addition to extensive comminution, there is serious injury of the muscles, integument, or other important textures ; to do so would only be to trifle with the safety of the case. Severe fractures, the result of gunshot injury, nearly always demand primary amputation, especially when they occur on the battle-field.

Secondary amputation may be required when, after an attempt to save a limb, and the employment of suitable antiphlogistic remedies, the parts become gangrenous; or when the consolidation of the fracture is prevented by profuse suppuration, and the patient is gradually worn out by diarrhœa and colliquative sweats. In the first case, the operation is performed as soon as the mortification is arrested, and there is a distinct line of demarcation between the dead and living parts ; in the second, as soon as it is perceived that the suppuration cannot be arrested, and that the patient has still sufficient strength to bear the pain and shock which must necessarily attend its performance.

4. INCOMPLETE FRACTURES OR BENDING OF THE BONES.

The bones are liable not only to break, but also to bend, as seen in figs. 433 and 434. Such an accident can only happen in young subjects, principally infants and children, in whom the osseous tissue, containing a preponderance of animal matter, is comparatively soft, flexible, and elastic. Bending of the bones of the skull, especially the frontal and parietal, is occasionally witnessed at an early age, as an effect of external violence, as that, for instance, produced when a child falls, head foremost, down a flight of stairs, or out of a second-story window upon the pavement below. Under such circumstances, the cranial bones, at the part struck, are depressed beyond their natural level, and yet there is not, so far as can be ascertained, any fracture, strictly so called ; they are merely bent or indented, and, if no untoward occurrence take place, they will, generally, in the course of a few days, resume their proper position

Fig. 433.

Fig. 434.

Incomplete Fracture of the Bones of the Forearm.

by their own resiliency, aided, doubtless, by the locomotive action of the brain, propelling them outwards away from its surface. In an adult, an accident, capable of producing such a result, would almost inevitably lead to fracture of the skull, probably of a very grave character, for the reason that the cranial bones, after a certain time, are always loaded with a quantity of earthy matter, in the form of carbonate and phosphate of lime, the presence of which renders them more or less brittle, and thus predisposes them to fracture. This tendency to fracture increases in proportion as we advance in years, and is, consequently, most distinctly marked in old age and decrepitude, in which the osseous tissue, almost destitute of animal substance, generally yields under the slightest force, the accident frequently eventuating in incurable injury.

Bending of the bones was incidentally observed by a considerable number of practitioners in the last century, and, indeed, even prior to that period ; but the first systematic account of it was published in 1810, by Professor Jurine, of Geneva. In 1821, it was described

by Dr. John Rhea Barton, and since then it has been carefully investigated by Professor Hamilton and other surgical pathologists.

I have myself met with this accident in ten cases, in children whose ages varied from three to eleven years, three being girls, and the other seven boys. Although it is most common in the ulna, radius, and clavicle, it also sometimes occurs in other pieces of the skeleton, as the humerus, femur, tibia, fibula, and ribs. External violence alone is capable of producing this lesion. I am not acquainted with any cases in which it was occasioned by muscular action. In fact, considering that bending of the bones is exclusively confined to children, it is hardly possible that the accident could arise from such a cause; certainly not, unless there existed extraordinary muscular development with remarkable flexibility of the osseous tissue, a condition hardly compatible with a healthy state of the system. In the bones of the forearm, which suffer more frequently than any other, the injury usually originates from force applied indirectly, as, for example, when a child, in the act of falling, instinctively throws out the arm to protect the body, and so receives the shock upon the hand, the concussion concentrating and exploding upon the radius, or the radius and ulna. In one of my cases, the bend was produced by the body of the child being suddenly propelled against the forearm at a moment when the elbow was planted upon the floor, and the wrist was lying upon a stool. Flexion of the clavicle is the result either of direct violence, or of force applied to the top of the shoulder, especially if the body is at the same time propelled in the opposite direction, as in the case of a fall.

The seat of this lesion is variable; in the long bones, as those, for instance, of the forearm, it usually occurs a short distance below their middle, but it may also take place higher up, or farther down. The radius and ulna may both suffer synchronously, but very frequently one alone is affected; or, if both are implicated, they do not suffer in an equal degree.

Judging from the cases of this accident that have fallen under my observation, I am induced to believe that it generally takes place without any particular predisposition, either local or constitutional. In every instance of the kind, the subject of the injury was in good health at the time of its occurrence. An exception, however, must be made in regard to the bones of rachitic children, in which incomplete fractures are always preceded by softening.

What is the precise nature of this lesion? Is it really, as the name implies, a mere bending of the bones, or is it a flexion combined with partial fracture? These questions are easily answered. In very young subjects, as in children not more than a few years of age, and in the milder forms of the lesion, the osseous fibres are merely extended or stretched, so as to permit themselves to be drawn out of their natural course; in cases of an opposite character, on the other hand, there is no doubt, that while some of the fibres are bent, others are both bent and broken. These conclusions are beautifully borne out by the experiments of Dr. Hamilton upon the bones of young chickens, which, from the fourth to the sixth week, and, consequently, before the completion of the ossific process, could readily be bent without fracture to an angle varying from twenty-five to thirty-five degrees; whereas the bones of older chickens, thus treated, always partially broke, their fibres being incapable of withstanding the force used in flexing them.

These partial fractures, sometimes called interperiosteal, from the fact that the periosteum remains intact, bear a close resemblance, in the mode of their production, and the nature of the resulting injury, to the appearances presented by a green hickory stick, forcibly bent over the knee, but not to such an extent as to occasion any external sign of fracture, although it will be found, upon making a section of the wood, that many of its fibres have actually been broken, while others, and, perhaps, the greater number, have merely been bent. These appearances are well shown in fig. 435, from Fergusson.

Fig. 435.

The symptoms attendant upon this accident are pain and deformity at the seat of the injury, loss of power in the limb, and absence of crepitation. The pain varies in degree, being sometimes slight, at other times severe; swelling soon supervenes, and the part feels numb and heavy. A marked curvature, generally very gentle, but occasionally quite abrupt, always exists at the affected part, and can seldom be completely effaced without the application of very considerable force; indeed, often not without breaking the bone entirely across, especially if it was partially fractured previously. In the latter case, there is usually at the convexity of the curvature a slight depression, capable of receiving the point of the
Case mentioned by Fergusson.

finger, its boundaries being formed by rough, sharp, bony fibres. Further than this there is no displacement, and under no circumstances is there any crepitation. The use of the limb is always greatly impaired, but not completely destroyed, as it commonly is in ordinary fracture. Finally, I may mention, as another highly important and diagnostic sign, the great difficulty which is so frequently experienced in restoring the parts to their proper position.

The *treatment* must be conducted upon the same general principles as in ordinary fractures. When the bones are merely bent, slight pressure and extension usually suffice to accomplish restoration, the affected parts being compelled, as it were, to retrace their former steps. If flexion be conjoined with partial solution of continuity, the reduction will necessarily be more difficult, and may, in fact, altogether fail, owing to the manner in which the osseous fibres are interlocked with each other, and the inability which is experienced in disengaging them, so as to induce them to slip back into their proper position. However this may be, the attempts to remove the curvature by extension and pressure should neither be too violent nor too long continued, lest they prove injurious. The object should be to restore as much as possible by gentle means ; what cannot be effected in this manner may well be left to the operation of time, the absorption of the broken and resisting osseous fibres, and the action of the muscles, which seldom fails to reinstate the parts, although from six to eight weeks may elapse before the final completion of the cure. I have generally found the use of leather splints, well padded, and accurately shaped to the limb, of great service in bringing the bones into their proper relations. Pressure with the elastic bandage, as suggested by Dr. H. A. Martin, of Boston, will also be found to be very useful. When the accident is followed by grave inflammation, the usual antiphlogistic remedies, especially leeching and cooling lotions, will be required.

There is a variety of partial fracture, known by the term *fissure*, which is peculiar to the bones of elderly subjects, no well-marked instance of it having ever been met with in infants and children. Such an occurrence, which is generally much more interesting in a pathological than in a practical point of view, is by no means uncommon in the skull, especially along its base, where it is always associated with severe, and frequently fatal, injury of the brain and its envelops. The fissures in many of these cases are most extensive, involving the sphenoid, occipital, temporal, frontal, and, perhaps, even the ethmoid and parietal bones. In the other pieces of the skeleton the occurrence is more rare ; but examples are occasionally seen both in the long, short, and flat bones, as the result of external violence, generally directly applied. The accident is, now and then, produced by gunshot injury. The lesion, however induced, consists essentially in a forcible separation of the osseous fibres, and exhibits itself in a great variety of forms, the crack sometimes extending through the entire thickness of a bone, at other times merely through its outer table, and at other times, again, involving both the compact and areolar tissues,

Fig. 436.

Hyperostosis after Greenstick Fracture.

but not passing completely through them. The length of the fissure varies from a few lines to a number of inches, perhaps as many as six or eight, although this is exceedingly uncommon. The width of the crevice is generally very slight, perhaps barely sufficient to admit the blade of a penknife. In rare cases, as when it involves the extremity of a bone, it may gape somewhat, so as to give the part the appearance as if it consisted of two fragments, firmly adherent at one end. Finally, the fissure may be straight, curved, or angular.

Of the rarity of this lesion, as an uncomplicated occurrence, an idea may be formed when it is stated that there are probably not more than three or four well-marked specimens of it in all the osteological cabinets of this city. As a conjoint affection, it is occasionally met with in compound fractures, especially when caused by railway accidents. There are no signs by which the nature of the injury can be distinguished during life ; a circumstance which is the less to be regretted, because the treatment does not differ from that of ordinary wounds, fractures, and contusions, with which it is so generally associated.

Bryant has described a rare case of deformity, fig. 436, consequent upon a green-stick fracture of the leg, in which the bones were allowed to remain in the position into which they were thrown by the accident. The tibia and fibula measured six inches across the centre, owing to the deposit of a large quantity of osseous matter in the concavity of the arch.

5. EPIPHYSEAL FRACTURES.

The extremities of the bones of young subjects are united to their shafts or bodies by means of cartilaginous matter, which, in some of the pieces, and in some individuals, does not assume the osseous form until after the twenty-first year, and occasionally, indeed, not until even a later period. Up to this time, consequently, these junctions are liable to be severed, so as to allow the contiguous extremities to separate from each other, and it is this occurrence which constitutes what is technically called diastasis, as seen in fig. 437; an affection first accurately described nearly at the same time by Roux and Guéritin.

Fig. 437.

Diastasis of the Femur: reunited.

It is probable that this accident may occur in all parts of the skeleton united in this manner, although there are, doubtless, some in which it is more common than in others. Its occasional existence has been recognized, by dissection, in the humerus, radius, femur, and tibia, and there are few systematic treatises that do not allude to it as being now and then met with in some of the other bones. The most common cause of diastasis is a wrench of the part, violent traction, or a severe fall. I am not aware that it has ever been produced by muscular action; and, on the other hand, it is rarely the result of direct violence, as, for instance, the kick of a horse, or the passage of the wheel of a carriage, such an accident more generally eventuating in fracture of the bones than in a separation of their epiphyses. The lesion may happen at any period of life, prior to the completion of ossification, but is most common from the fifth to the fifteenth year. Its occurrence in middle-aged and elderly subjects is, for the reasons already mentioned, impossible. Girls are more prone to it than boys, owing, probably, to the fact that they are more frequently exposed to its exciting causes. The affection, like fracture, may be simple, compound, or complicated. Cases are noticed in which the diastasis is blended with fracture of the shaft of the bone, and it is by no means uncommon to find that small processes of bone are dragged away with the epiphyses.

The symptoms of this lesion do not differ essentially from those of fracture, properly so called. Its existence may generally be suspected when an accident affecting a bone occurs in a young subject, in the neighborhood of a joint; when the ends of the fragments are transverse, or nearly so; when the articular piece retains its position, while the other moves about; and, lastly, when the crepitation produced by rubbing the ends of the fragments against each other is of an unusually dull, rough, grating character. Moreover, it will commonly be found that the parts, when once reduced, are less liable to be dragged asunder by the action of the muscles than in an ordinary fracture.

The prognosis is generally favorable, union commonly taking place very promptly, especially in very young subjects. The accident, if neglected, or unskilfully treated, is liable to be followed by severe inflammation, abscesses, erysipelas, and more or less deformity. The treatment is the same as in ordinary fractures.

6. UNUNITED FRACTURES.

Fractures occasionally refuse to unite, either in consequence of causes inherent in the part or system, or on account of mismanagement growing out of the surgeon's want of attention and skill, or else out of the patient's own misconduct. It is practically important that a distinction should be drawn between a fracture that unites tardily and one that does not unite at all, or only through the medium of fibrous, ligamentous, or fibro-cartilaginous tissue. Slow consolidation is by no means uncommon; the parts may be loth to take on the requisite degree of ossific action, and the result may be that a fracture that is ordinarily repaired in four or five weeks, may, perhaps, be still imperfectly united at the end of twice that period. The process of restoration is only held in abeyance, neither advancing nor receding; by and by it begins again, and then often proceeds with its wonted rapidity. Such cases are frequently very trying to the surgeon's patience, although they generally turn out well in the end, provided sufficient care has been taken to preserve the parts in their proper relations. In the ununited fracture, on the other hand, the process of consolidation is either completely thwarted, or, after having made some progress, is at length permanently arrested. Under these circumstances, the ends of the fragments are gradu-

ally rounded off by absorption, and remain either entirely loose and unconnected, or they become adherent through the medium of fibrous, ligamentous, or fibro-cartilaginous

Fig. 438.

Ununited Fracture of the Bones of the Leg.

matter. Sometimes, although rarely, an adventitious joint is formed, as in fig. 438, provided with a more or less distinct synovial membrane, thus permitting the ends of the bone to move upon each other with great facility.

The bones most liable to non-union after fracture are those of the arm and thigh. Of 150 cases collated by Dr. George W. Norris, 48 related to the humerus, 48 to the femur, 19 to the forearm, 33 to the leg, and 2 to the lower jaw. Bad injuries of this kind of the clavicle, rendered so by severe contusion and great displacement of the ends of the fragments, are often followed by imperfect consolidation. The occurrence of non-union, however, of fractures generally is probably much less frequent than is usually supposed. Of nearly 4000 cases treated in the Middlesex Hospital, London, there were, as stated by Lonsdale, only five or six of non-union. Of 946 cases of recent fractures admitted into the Pennsylvania Hospital, from 1830 to 40, not an instance of the kind occurred; and of 367 cases, treated in the Massachusetts General Hospital, there was, according to Dr. Moreland, only one in which a false joint had formed. Within the last few years not less than five cases of this kind have come under my observation, three of them in the Jefferson College Hospital.

Want of reunion in a fracture may depend upon a great variety of *causes*, some of them inherent in the parts themselves, others connected with the system. Thus, it may be occasioned by the interposition of a clot of blood or of a piece of muscle, tendon, or bone. An instance is recorded where the consolidation of a fracture was prevented by the presence of a musket ball; and Dupuytren observed a fracture of the humerus, in a man, twenty-three years of age, in which a similar effect was produced by the lodgment of a large number of hydatids. Fragility, softening, and other affections of the bones, are usually enumerated as circumstances interfering with the reparative process, but it is not improbable that their influence has been greatly exaggerated : at all events, it is certain that in many cases of this kind the fracture unites as readily as when the bones are perfectly healthy. Too much motion, the long-continued use of cold water, especially in persons of a nervous, irritable temperament, and tight bandaging, may also bring about this result. Many years ago, I saw a case in which, from the latter cause, the consolidation of a fracture of the thigh-bone was delayed for nearly twelve months. The limb had become excessively atrophied from the protracted and injudicious employment of the roller, and it was not until after the bandage had been entirely laid aside, and the man permitted to exercise upon crutches in the open air, that nature fairly began the process of repair.

Old age is no barrier to reunion, if the patient is in good health at the time of the accident, and the fracture, unattended by complications, is properly treated. I have met with several cases of fracture of the humerus, in persons after the eightieth year, followed by complete consolidation in the usual time ; and Dr. W. W. Dale has reported one in a lady of one hundred, in which the union was equally prompt and satisfactory. A fracture of the upper third of the thigh, in a woman, ninety-three years old, treated by Dr. J. K. Holloway, of Ohio, was completely consolidated in seven weeks.

The most common of all the local causes of tardy reunion, in injuries of this kind, are motion and imperfect apposition of the ends of the fragments. Either of these circumstances will inevitably interfere with, if not effectually prevent, the consolidating process, however favorable to a cure the condition of the system itself may be. Hence, as stated elsewhere, the absolute necessity, in every fracture, of carefully guarding against those occurrences until the process of repair is so far advanced as to enable the fragments, so to speak, to take care of themselves.

Fractures situated at or near the entrance of the nutrient arteries unite less rapidly than such as are situated further off, as they interfere more or less with the circulation

and nourishment of the osseous tissue. It is easy to suppose that the laceration of these vessels, as occasionally happens both in simple and compound fractures, might be a cause of non-consolidation, especially when conjoined with other unpropitious circumstances. Statistics show that, when the supply of blood is cut off, to any considerable extent, so as to impose upon the periosteum the exclusive duty of nourishing the fragments, either one or both pieces will become atrophied, their walls being visibly thinned and their areolar structure rarefied.

Inadequate supply of nervous fluid may be a cause of non-union. A case reported by Mr. Travers beautifully illustrates this point. A patient had a fracture in the arm and another in the leg, complicated with an injury of the spine which palsied the lower half of the body. The broken humerus readily united, but the tibia and fibula refused to heal.

Want of union is sometimes dependent upon the absorption of the ends of the fragments, or even of the greater portion of the fragments themselves, as in a very singular case which came under my observation in a man, fifty-three years old. At the age of eighteen, he received two simple fractures of the right humerus, at an interval of three months, one being situated about the middle of the bone, the other an inch and a half higher up. The first was repaired in the usual time, but the second refused to unite, the ends of the fragments becoming rounded off, as in the formation of an artificial joint; the process gradually proceeding, the whole bone was finally absorbed, nothing remaining except the condyles and a little of the head. The period occupied in the absorption was about six years, the general health being all the while unimpaired. The muscles of the arm are well developed, and are capable, when thrown into powerful action, of diminishing the interval between the shoulder and elbow to an extent of several inches. Although the man is unable to perform any of the usual movements of the limb, he can readily raise a weight of upwards of one hundred pounds, and can apply his hand to various purposes. The accompanying cut, fig. 439, represents the appearance of the arm during the contraction of its muscles.

Fig. 439.
Absorption of the Humerus.

The principal constitutional causes which interfere with the reparative process are, debility, whether from loss of blood, want of nutritive action, or exhausting disease, as long-continued fever, a gouty, rheumatic, scorbutic, rachitic, or syphilitic state of the system, and loss of nervous influence, however induced. Pregnancy has sometimes been accused of preventing union, on the ground that the nourishment required by the fœtus establishes too great a drain upon the blood; but in the few cases of this kind that have fallen under my observation, I have not witnessed any such effect, and I am strongly inclined to believe that this influence has been greatly exaggerated, if, indeed, it is not wholly chimerical. The same remarks are applicable to suckling. Another cause, probably much more efficient, as well as much more common, is the protracted and inordinate use of ardent spirits, exhausting the nutritive energies of the system, and rendering the blood and its vessels unfit for the performance of the important duties assigned to them in the reparative process.

Treatment.—Whatever the cause of the non-union may be, every effort should be made to discover it, with a view to its early and efficient rectification. Nutritious food and drink, as porter, ale, wine, or brandy, aided, if necessary, by tonics, more especially iron and quinine, will be required if the patient be very weak or anemic. A gouty or rheumatic state of the constitution is best remedied by purgatives, alkalies, and colchicum. Syphilitic symptoms must be met with the iodides, in union with mercury, the latter of which should sometimes be carried to the extent of slight ptyalism. Debility from drunkenness must be counteracted by the judicious employment of the patient's accustomed stimulants.

Sometimes a change of air is very serviceable, especially such as attends upon a sea-voyage. An army surgeon, stationed in the West Indies, had under his care six cases of fracture which remained ununited for a long time, but were all promptly cured on being sent to Europe.

The local treatment must be regulated by circumstances. The precise cause of the tardy or imperfect union must, if possible, be clearly ascertained, and promptly remedied by appropriate measures. If any motion exists perfect quietude must be insured; any defect of contact must be redressed by a more accurate adjustment of the ends of the frag-

ments; cold applications, if injurious, must be discontinued; and any extraneous intervening substance must be removed, either through the agency of the absorbent vessels, by pressure and other means, or, as in the case of a piece of dead bone, with the knife and forceps. The cause of the defective union having been thus remedied, the case will be likely, of its own accord, to proceed to a favorable termination, the ordinary principles of treatment being, of course, observed.

A large number of local remedies have been employed for the cure of united fractures. Among these the most important are friction, compression, vesication, acupuncturation, cauterization, subcutaneous division or perforation, the use of setons and ivory pegs, and excision of the ends of the fragments.

1. Cutaneous friction, either dry or moist, by means of the bare hand, or with a piece of rough cloth is sometimes serviceable, especially in the more simple cases; if moist, various liniments, lotions, or unguents may be employed, often with decided benefit, inasmuch as they tend to excite capillary action in and around the ends of the fragments, thus promoting the formation of callus.

2. Compression is occasionally worthy of trial. It may be made with splints of leather, felt, or binder's board, and the bandage; or by an apparatus expressly constructed for the purpose, and so arranged as to concentrate the pressure at the seat of the fracture. It must be steady and persistent as well as uniform and gentle.

3. Blisters and iodine now and then act beneficially. Their application is particularly indicated when the want of union is dependent upon undue vascular excitement, and is, of course, entirely restricted to cases of recent standing.

4. Friction of the ends of the fragments against each other was recommended by Celsus, and has often been successfully practised by modern surgeons. It should be performed very gently, and be repeated every four, six, or eight days, according to its effects.

5. Percussion of the ends of the fragments, originally recommended by H. O. Thomas, of Liverpool, has been successfully employed in some cases of ununited fractures, more especially in cases of recent standing. The skin at the seat of the fracture being protected with felt or sole leather, and the patient placed under the influence of an anæsthetic, the ends of the broken bone are smartly struck five or six minutes with an iron hammer. The operation is followed by a good deal of swelling, which, however, promptly disappears under local treatment.

6. Acupuncturation with a long, slender needle may be tried; or a small incision may be made over the seat of the injury, and a heated wire thrust between the ends of the fragments. The galvanic cautery might, perhaps, occasionally be employed with advantage, especially when a more powerful excitant is needed.

7. Cauterization of the integument over the seat of the fracture with some caustic alkali, was recommended and successfully employed, in 1805, by Dr. Hartshorne, of this city. Sometimes the ends of the bones may advantageously be exposed, and rubbed over with nitrate of silver, although such a proceeding is not always devoid of danger.

8. Subcutaneous division of the ligamentous bands between the two ends of the fragments has been successfully practised. The operation is performed with an ordinary tenotome, used in such a manner as to cut the parts as thoroughly as possible, especially over the extremities of the broken pieces.

Fig. 440.

In very recent cases, such a procedure is occasionally followed by a good cure. In using a tenotome for such a purpose care must be taken not to wound any important vessels or nerves.

9. The injection of five to ten drops of glazial acetic acid between the ends of the fragments, in cases of recent standing, has been successfully employed by Fitzgerald. The fluid acts, as is supposed, by softening the interposed fibrous tissue, and thus placing it more readily under the influence of the absorbent vessels. The smarting pain which follows the operation always speedily subsides of its own accord.

10. The introduction of ivory pegs was originally proposed by Dieffenbach. They are from an inch and a half to two inches in length, conical in shape, and inserted into the ends of the fragments, previously pierced with a gimlet, such as that sketched in fig 440. They must be forcibly driven into the openings, and retained until the consolidating process is well advanced. Excellent and rapid cures have repeatedly followed this plan in my hands.

11. The seton, introduced into practice in 1802, by Dr. Physick, is ordinarily, in
obstinate cases, a very reliable, but not always a safe method, as it is liable to give rise to erysipelas and other bad consequences. It should be passed by means of a long, thin, flat needle, sharp and lancet-shaped at the point, between the ends of the fragments; or, if this be impracticable, as close to the site of the fracture as possible, for experience has shown that the operation, thus performed, is nearly as successful as the usual procedure. The foreign body, a piece of elastic tape, silk ribbon, or French braid, is generally retained until it has excited slight suppurative action. The patient is carefully watched, the seton being at once withdrawn, if the pain and swelling become at all severe. Immediately after the introduction, the fragments are properly adjusted, and steps taken, if necessary, to maintain extension and counterextension. In the first case in which this treatment was employed, the seton was retained many weeks, and the patient recovered the perfect use of his limb. The practice of withdrawing the seton at the end of a few days, as is occasionally advised, is objectionable, for the reason that it will hardly have sufficient time to excite the requisite degree of inflammatory action.

12. Perforation of the ends of the bone by means of a special instrument, fig. 441, an operation proposed, in 1853, by Professor Brainard, is sometimes serviceable. It consists in piercing subcutaneously the extremity of each fragment at several points, and cutting

Fig. 441.

Brainard's Perforator.

up the intervening tissue, with a view of exciting ossific action. The instrument should have an immovable handle. A preliminary puncture is made with the bistoury, and any hemorrhage that may arise is controlled by compression. The operation is repeated every eight, ten, or twelve days until consolidation has occurred, the limb being in the mean

Fig. 442.　　　　　Fig. 443.

Gaillard's Fracture-pin.

time kept quietly at rest in splints, and the treatment being in other respects conducted upon general principles. From what I have seen of the effects of this treatment, I am satisfied that it is adapted chiefly to cases of delayed union, and that it is altogether inadequate in those of long standing.

13. Connecting the ends of the fragments together subcutaneously by means of an iron screw, as originally practised by the late Professor Pancoast, in 1857, often succeeds where the more ordinary plans prove abortive. Indeed, I know of no method of treatment that is so effective and at the same time so perfectly free from danger as this in old ununited fractures and in recent false joints. It is particularly suited to ununited fractures of the femur and humerus, but is not so well adapted to those of the leg and forearm, in which it occasionally fails. The instrument, fig. 442, with which the operation is performed, is shaped somewhat like a gimlet, and is provided with a movable handle. A puncture being made down to the seat of the fracture with a long, narrow bistoury, the screw is carried through the end of one fragment into that of the other, and retained until there is complete consolidation, from six to eight weeks being usually required to accomplish the object. When the treatment is over, the instrument may be removed; or, if it do not cause any inconvenience, it may be permanently left, the more especially when it is completely buried beneath the skin. Its presence is rarely, in any case, productive of

Iron Screw for connecting the Ends of Ununited Fractures.

serious inconvenience. Now and then slight erysipelas arises after the operation, but this generally soon disappears of its own accord. In the seven or eight cases in which I have employed this treatment the success in all was complete. In three of these cases the screw was retained upwards of four months. Such a procedure will not be likely to succeed well when an artificial joint exists.

Dr. E. S. Gaillard has invented a fracture-pin, fig. 443, provided with a silver sheath and brass nut, which is tightened after the instrument is firmly buried in the ends of the fragments. The contrivance does not, apparently, possess any advantages over the screw above described.

14. The method of scraping the ends of the bone, through an open wound, introduced at an early period of the profession, and occasionally practised in modern times, is an inefficient procedure, and should, therefore, be abolished, the more especially as it is not always by any means free from danger.

15. Finally, as a dernier resort, excision of the ends of the fragments, as originally performed in 1760, by Mr. White, of England, may be practised; but it should be borne in mind that the operation is not only difficult of execution, but that it is by no means devoid of danger, more especially when it is performed upon the thigh, where it has occasionally proved fatal. A very free incision is made through the soft parts down to the ends of the broken bone, which are then carefully liberated, brought out at the wound and retrenched, either with a stout knife, a saw, a pair of pliers, or the surgical engine. Sometimes the mere removal of the cartilaginous incrustation is sufficient, an object which may be easily accomplished with a scraper.

To maintain the freshened ends in accurate and steady apposition, it was proposed by Horeau, in 1805, to connect them together by means of wire, retained until the completion of the cure. The procedure has been frequently employed in this country, in consequence, apparently, of the high authority of the late Dr. J. Kearney Rodgers, of New York, who was the first to perform it on this side of the Atlantic. It consists, first, in cutting off the rounded ends of the fragments; secondly, in drilling a hole through each; and, lastly, in tying them firmly together with a silver wire composed of five or six ordinary suture threads, so as to keep them closely and evenly in contact during the consolidating process. It is generally imagined that this procedure is necessarily followed by violent inflammation, jeoparding both limb and life; but this is an error. If the operation be carefully performed, and the after treatment properly conducted, I believe that it will commonly be found to be entirely free from danger, while the utmost confidence may be placed in its efficacy. In nearly every instance in which I have employed it, very little pain, inflammation, or fever occurred, and the result in all, except one, was most satisfactory. The operation is, of course, less dangerous in the upper than in the lower extremity, where, especially if the bone be thickly covered with muscles, it is often attended with great difficulty. When the false joint is situated very high upon the femur such an undertaking is altogether out of the question.

In the first case in which I tried this plan, the fracture occupied the inferior fourth of the shaft of the humerus, and various remedies, among others Dr. Brainard's, had been faithfully but fruitlessly employed. The patient, a man, twenty years of age, being thoroughly anæsthetized, a longitudinal incision, about three inches in length, was carried along the posterior aspect of the arm, through the triceps muscle, over the site of the fracture. The lower fragment was found to overlap the upper about one inch and a half. The ends of the bone were surrounded by a strong fibrous membrane, which was firmly adherent to the neighboring parts, and formed a sort of shut sac, in which the bone was imbedded. About an inch of the lower portion of the upper fragment, and half an inch of the upper portion of the lower fragment, were removed with a delicate saw; but on account of their firm adhesions, and especially the shortness of the inferior piece, some difficulty was experienced in bringing them fully into view. The fragments were conical, rounded, smooth, and invested by a thick, fibrous periosteum: no synovial membrane or fluid existed. The next step of the operation consisted in drilling a hole into each extremity of the bone with a common gimlet, when a piece of wire was introduced to maintain them in apposition. The ends of the wire were twisted together, and allowed to protrude from the wound, the edges of which were approximated by three sutures and adhesive strips. Two splints and a roller being applied, the arm was firmly supported in a sling. There was very little hemorrhage, and no vessels required ligation. As the patient suffered great pain, a grain of morphia was given immediately after the operation. Very little local or constitutional disturbance followed, and nearly the whole wound healed by the first intention. At the end of the eighth week, the union had advanced so far that there was scarcely any perceptible motion. In a fortnight after, the wire was removed,

and the patient went home perfectly restored, the arm being about an inch and a half shorter than the sound one. Under the influence of frequent passive motion, the elbow-joint was gradually regaining its functions.

In another case, that of a man, thirty-two years of age, I treated with equal success, by an operation of this kind, an ununited fracture of the humerus of twenty-seven months' standing. The ends of the fragments were connected by two silver wires, which were permanently retained. The case is reported at length in the North American Medico-Chirurgical Review for July, 1861.

In performing excision, it is very important that the periosteum should not be stripped off the ends of the bone. In a case in which this accident happened to me through the carelessness of an assistant, violent erysipelas with some necrosis was the consequence, endangering the safety of both limb and life.

Professor Henry J. Bigelow, in 1867, published the results of eleven cases of ununited fractures, successfully treated, with one exception, by connecting the excised extremities of the bones with silver wire, great care being taken to preserve the periosteum; a precaution to which he very justly attributed much of the happy effects of the operation.

The results of some of the above operations have been placed in a striking and interesting light by the statistics of Professor Agnew. Thus, of fifty-three cases in which manual friction was used, twenty-five were cured. Of eighty cases treated by mechanical appliances, fifty-seven were cured, and two died. Of seventy-three cases in which the seton was used, twenty-seven were cured, and two died. Of forty-nine cases of immobilization, twenty-seven were cured, and one died. Of one hundred and seventy-eight cases of resection, with its modifications, one hundred and four were cured, and eleven died. Of one hundred and eleven cases of drilling, with its modifications, sixty were cured, and one died. It is worthy of remark that the treatment by the seton is more successful in fractures of the femur and humerus than in those of any other bones. The danger of the more severe operations, especially the seton and resection, follows the same laws as in amputations, increasing with the size of the limb and its proximity to the trunk. Of the seventeen deaths, eight occurred after resection and drilling of the ends of the bone in ununited fractures of the femur; and the operation should, therefore, always be performed with the utmost care.

Whatever plan of treatment be adopted, it is impossible to be too attentive during the after-management of the case, especially in securing repose and accuracy of apposition to the ends of the fragments. As soon as the immediate effects of the operation have passed off, the limb should be incased in the immovable bandage, with an opening opposite the wound for facilitating drainage, and the patient should be permitted to exercise in the open air upon crutches, if the fracture be seated in the lower extremity; the general health should be properly cared for, and every means employed to assist nature in her efforts in effecting a cure. In incurable cases of ununited fracture, or in a false joint consequent upon fracture, the patient will derive great comfort from wearing the admirable contrivance devised for this purpose by Dr. Henry H. Smith, of this city. The apparatus, delineated in fig. 444, is constructed upon the same principles as the ordinary club-foot apparatus, consisting of a shoe, and of a leg and a thigh-piece, connected by hinges, and fastened round the limb by straps and buckles.

If any of the more severe operations are performed, the treatment, for the first few days, must be strictly antiphlogistic, the patient being most carefully watched, lest the inflammation, running too high, produce fatal consequences. If abscesses form, they should be promptly opened, and the utmost attention should, throughout, be bestowed upon cleanliness. The great danger to be apprehended after such operations is from erysipelas, pyemia, and phlebitis.

When all the known remedies, after a thorough trial, fail, and the limb is utterly useless, the only resource is amputation. Few cases, however, demanding such a terrible alternative, will be likely to arise in the present state of the science.

Fig. 444.
Smith's Apparatus for Ununited Fracture, modified by Kolbé.

7. VICIOUS UNION OF FRACTURES.

From inattention of the surgeon, or a want of coöperation of the patient, the ends of a broken bone sometimes unite in a very unseemly and injurious manner, entirely at variance with the beauty and usefulness of the affected limb, as represented in fig. 445. The deformity thus arising may be produced by the overlapping of the extremities of the fragments, attended, of course, with corresponding shortening; or, it may be owing to the imperfect contact of the two ends, thus occasioning a certain amount of angular displacement, without any abbreviation of the length of the bone. In whatever way the deformity may be induced, it is obvious that it should be rectified at the earliest possible moment; for the longer a case is permitted to remain on hand, the more difficult it will be to afford relief. There are
Fig. 445.

Viciously united Fracture of the Leg.

several procedures by which this object may be attained: 1st. Compression and extension; 2dly, forcible flexion, or rupture of the callus; 3dly, subcutaneous division of the connecting medium; and, lastly, resection of the ends of the fragments. These methods are not, of course, all equally adapted to every case.

1st. The safest as well as the most simple procedure, but one which is applicable only in the more early stages of vicious union, consists in applying pressure opposite to the seat of the deformity, in the direction of its convexity. This may be efficiently done by means of appropriate splints and bandages, or with special apparatus provided with pads and screws, and appliances for making extension and counterextension, particularly if there is marked shortening. It is not necessary to give any description of these contrivances, as they may be readily fabricated by any ingenious mechanic, or even by the surgeon himself. No preliminary treatment will be required. It is absurd to suppose that the callus may be softened by cataplasms and fomentations. The compression and extension should be made, at first, in as gentle a manner as possible, and be gradually increased and steadily maintained up to the point of easy tolerance, being occasionally intermitted if productive of pain, or likely to induce excoriation.

2dly. If the preceding method fail, or is inapplicable, forcible flexion and extension, or rupture of the callus, may be attempted, compelling the displaced fragments to retrace their steps. This plan is also chiefly applicable to recent cases, but has occasionally been employed at the end of six, eight, ten, or even twelve weeks. I have myself successfully employed it at the expiration of the second month, and repeatedly within the first three weeks. It would be difficult to state when it should be refrained from; much will necessarily depend upon circumstances, for in one case the union may be firm in a month, while in another, perhaps, equally simple, if not more so, twice or thrice that period may elapse before it is consolidated. Perhaps as good a guide as any would be the existence of slight mobility between the ends of the fragments; if the union is very strong, the attempt to break it might be attended with fracture of the bone above or below the seat of the callus, thus seriously complicating the case. Besides, the operation, except in the more simple forms of the affection, should not be undertaken without some preparation of the system, as it is occasionally followed by violent inflammation, erysipelas, abscess, and even death.

The operation is easily performed, before the union is consolidated, simply by bending the limb over the knee, or by placing it upon a table, and applying pressure upon the distal extremities of the fragments. When the case is of long standing, and the union firm, the callus can only be broken by the employment of force applied by some special apparatus, designed either to act directly upon the callus, or by means of a weight appended to the distal extremity of the bone, the fractured part projecting slightly over the edge of the table, while the portion of the limb containing the upper fragment is carefully held down by assistants. One of the best of the various contrivances devised for this purpose is that of Butcher, fig. 446, the force of which can be made to bear

directly upon the displaced angle of the broken bone. It has been ascertained by experiments, performed by Jacquemin, Bosch, Œsterlen, and others, that the callus of a thigh-bone, broken fifty days previously, requires a weight of fifty to sixty pounds to sever the fragments at the seat of the callus.

3dly. When the union is complete, and the preceding methods have either failed or are inapplicable, partial division of the bone should be practised, the object being to weaken it in such a manner as to admit of its more ready fracture, or gradual bending by systematic compression, as the new osseous matter becomes softened from the effects of the inflammation consequent upon the operation. The perforation is effected subcutaneously by means of a suitable drill, or, what is better, a very narrow chisel. If it be intended to break the bone, this should be done at once, and the limb immediately placed in a suitable apparatus. If, on the other hand, the rectification is to be effected by bending, no formal measures, for this purpose, should be adopted for the first eight or ten days, or until the osseous tissues have undergone a certain amount of softening.

4thly. Other means failing, the only resource is excision of the bone at the seat of the fracture, along with a portion of the callus. The procedure, which took its rise in the early part of the sixteenth century, consists in exposing the extremities of the broken bone, and removing, with the saw or pliers, a sufficient piece to admit of the accurate coaptation of the raw surfaces. The case is afterwards treated as one of ordinary compound fracture.

Finally, when relief is impracticable by any of the means now described, and the limb is

Fig. 446.

Butcher's Clamp for Refracturing badly set Bones.

sadly in the way of comfort and usefulness, the individual being, perhaps, obliged to labor for his daily subsistence, the only alternative is either to abandon him to his fate or to resort to amputation.

In 1851 I met with an instance of compound fracture of the tibia, in a young man of nineteen, in whom about two inches of that bone, near its middle, had been shot away, two years previously, by a rifle ball. The fibula had remained intact, but with the aid of a stiff leather splint, forming a case which reached from just below the knee to within a short distance of the ankle, progression was performed with tolerable ease, although not without the use of a crutch. If the deficiency of bone had been somewhat less, I should have been tempted to cut away a portion of the fibula, and, after refreshing the ends of the tibia, to approximate the bones by means of splints, or silver wire, fully anticipating a good cure. Since this suggestion was thrown out, many years ago, this treatment has been carried into effect by the Professors Pancoast, who have reported several successful cases. Instead, however, of exsecting a portion of the fibula, they simply broke that bone opposite the fracture in the tibia.

8. DISEASES OF THE CALLUS.

Callus, like all new tissues, is liable to different diseases, both during its development and after its completion, more or less hostile to its welfare and perpetuity. Some of these affections have a local origin, some depend upon the state of the constitution, and others, again, seem to partake of the nature of both of these. Deficiency of callus, although not, properly speaking, a disease, may, nevertheless, become a source of great difficulty on account of its inability to subserve the purpose of a supporting medium. The causes which may induce this condition, and the means of remedying it, when it exists, have already been pointed out.

An exuberant callus is by no means uncommon; it occasionally arises without any obvious cause, but more generally it is dependent upon the separation of the ends of the broken bone, as if nature were determined to effect union, despite the neglect of the sur-

geon.   The annexed cut, fig. 447, from a drawing of a specimen in the collection of the late Professor Cobb, of the University of Louisville, affords a graphic illustration of an excess of this substance, obviously produced in this way.   The fracture, an oblique one, situated just above the middle of the right femur, had evidently occurred several years
Fig. 447.
Exuberant Callus after Fracture of the Thigh.

before death.   The callus, which was exceedingly porous as well as very brittle, was eleven inches in circumference at the widest part, by six inches in length.   From its superior extremity projected two processes, which overlapped the upper fragment, and must have materially impeded the action of the muscles of the limb.

An exuberant callus is occasionally produced by the presence of pieces of dead bone, which it thus imprisons as foreign bodies are sometimes inclosed by a cyst, or by a wall of plastic matter.   The sheath thus formed, however, is always imperfect, openings existing in different parts of its extent for the purposes, apparently, of drainage.   Neglected or badly-treated comminuted fractures, caused by gunshot, railway, and other severe injury, are not unfrequently followed by an extraordinary redundancy of callus; and as the effect of this substance is to incarcerate the fragments of the broken bone, profuse discharge, generally of an unhealthy, fetid, and sanious character, may be thus kept up for almost an indefinite period.   The proper remedy, obviously, is the extraction of the dead fragments, a procedure occasionally of a very embarrassing character, especially when the callus is situated in a bone thickly covered by muscles, or in close proximity with important vessels and nerves.   In a case under my charge many years ago, I removed not less than twenty-four pieces of this kind, some of considerable size, having previously made a long incision over the tumor in front of the thigh.   With the aid of chisels, gouges, and pliers, riddance was achieved with but little loss of blood, and with no pain, as the patient was thoroughly under the influence of chloroform.   Although the number of dead pieces was unusually great, such was the size and firmness of the callus that, notwithstanding it was obliged to be divided in almost every direction, no separation of the ends of the broken bone ensued, and the patient, after having recovered from the immediate effects of the operation, was able to walk about as before.   The fracture had been caused nine months previously by an escapette ball.   When exuberant callus exists in its more simple forms unaccompanied by dead bone, its removal may occasionally be effected by the persevering inunction with compound iodine ointment and other sorbefacient remedies.

An extraordinary degree of brittleness, arising from an excess of earthy matter, occasionally exists in the callus of a broken bone.   Such an event may occur at a comparatively early period, as a result of causes the true nature of which is not always easy of detection.   I believe, however, that fragility of the callus is more frequently met with in persons of a gouty, rheumatic, or syphilitic state of the system, than in any other class of individuals.   However induced, the slightest injury, as a mere twist of the bone, or even muscular exertion, is generally capable of fracturing it, and, consequently, of reseparating the ends of the fragments.

Callus is subject to *softening*, disintegration, and absorption, if not, also, to fatty degeneration.   The causes under the influence of which these changes are affected are not always, or, perhaps, even generally, distinguishable.   In some cases they are plainly owing to undue compression, as from tight bandaging; in others, they are induced by premature exercise, or the weight of the body causing undue pressure upon the callus.   Occasionally, the absorption is distinctly traceable to the inordinate use of mercury, carried to profuse salivation; or it may depend upon a syphilitic taint of the system, especially when this affection has reached its third stage, in which the bones and periosteum are so constantly, and often so seriously, involved.   But the most common cause, perhaps, of all, is an impoverished and diseased state of the blood, from a want of proper food and fresh vegeta-

bles and subacid fruits.   The influence of ill-health arising from this cause upon the condition of the callus was strikingly exemplified in Lord Anson's voyage to the Pacific Ocean, in which many of the crew suffered severely from scurvy.   It was noticed that those who had formerly had fractures were attacked with absorption of the callus, speedily terminating in separation of the ends of the broken bone.   Cicatrices, whether the result of the healing of wounds or of ulcers, experienced a similar fate, the parts breaking out into open sores, remarkably pale, languid, flabby, and difficult to cure.   Similar effects are occasionally observed to follow the attacks of typhoid fever and anemic states of the system, however engendered.

The treatment of softened and disintegrated callus must depend upon the nature of the exciting cause, due inquiry into which should, therefore, always be made as a preliminary step.   Tight bandages and splints are removed ; premature exercise is avoided ; iodide of potassium and mercury are administered if the cause is obviously of a syphilitic nature ; scurvy is relieved by a change of diet, especially by the use of subacid fruits and vegetables ; and anemia is met with tonics and stimulants, as iron and quinine, with milk punch and nutritious food.

Finally, callus is sometimes the seat of severe pain, generally of a dull, aching character, but occasionally very sharp, and recurring at every change of the weather, so that the part literally subserves the purpose of a barometer.   Persons of a gouty, or rheumatic predisposition, and those affected with tertiary syphilis, are particularly prone to suffer in this way.   Now and then the pain appears to be of a neuralgic nature.   The most accurately united fracture may be followed by such an occurrence, but it is by far most common in those in which there is a redundant or very irregular callus.   The cause of the pain has been variously explained.   The probability is that it is generally due to the pressure exerted by the exuberant substance upon the nerves in its immediate vicinity. This idea appears the more plausible when it is recollected that filaments of nerves of considerable size are sometimes imprisoned in the callus of a broken bone.

Among the more important remedies for the relief of this pain, are various sorbefacient and anodyne lotions, as acetate of lead and laudanum, tincture of iodine, chloroform liniment, and veratria ointment.   Sometimes a blister answers a good purpose.   When the pain is dependent upon a syphilitic taint of the system, the iodides must be employed, either alone or in union with mercury.   Colchicum will be useful when there is a gouty or rheumatic state of the system.   Excision of the callus might be required when it is obvious that the suffering is due to the presence of a compressed and imprisoned nerve.

SECT. XX.—FRACTURES OF PARTICULAR BONES.

1. HEAD AND TRUNK.

FRACTURES OF THE NASAL BONES.

Falls and blows are the causes of this fracture, which may be either simple or complicated ; oblique, transverse or longitudinal ; limited to one bone or extended over both. It is usually attended with severe injury of the soft parts, and sometimes with fracture of the ascending process of the superior maxillary bone.   Occasionally, again, there is a separation of the nasal cartilages, or fracture of the ungual bone, the ethmoid bone, the vomer, or the turbinated bone.   The symptoms are generally well marked, except when there is considerable swelling of the integument, when the nature of the lesion may easily be overlooked, perhaps much to the detriment of the patient.   If an examination be made soon after the occurrence of the accident, the nose will be found to be out of shape, from displacement of the fragments, one of which may be depressed towards the nostril, while the other may form an unusual prominence beneath the skin.   Crepitation is also commonly distinguishable, especially when the fracture is multiple, or the bone is broken into several pieces.   In all cases, the point of the finger should be passed over the surface of the nose, with a view of ascertaining whether there is any irregularity or mobility, as there will almost certainly be when there is a fracture.   If, after this, there be still some doubt, it will be well to introduce a large probe, metallic bougie, or grooved director into the nostril, for the purpose of making counterpressure, while pressure is applied in the opposite direction with the end of the finger.   When the bone is denuded by a wound, the diagnosis will seldom be difficult.

More or less bleeding generally attends this accident ; occasionally, indeed, it is very profuse, and in some instances it is said to have proved fatal.   Another symptom, some-

times present, is emphysema at the root of the nose, extending along the eyebrows. It usually comes on within a short time after the accident, and is owing to an escape of air from the nostril across a rent of the mucous membrane into the subcutaneous connective tissue. It is in itself of no moment, as it usually disappears spontaneously in a few days. An escape of tears is also an occasional occurrence. Sometimes violent cephalic symptoms attend these fractures, depending upon the intimate connection between the nasal and frontal bones, which permits the jarring effects of the blow or fall to be communicated to the brain and its envelops.

Fracture of the nasal bones is not always free from danger, although the patient generally recovers without any untoward symptoms. Danger to life is to be apprehended only when there is serious cerebral involvement, as when the lesion is associated with fracture of the cribriform plate of the ethmoid bone, separation of the dura mater at the anterior part of the base of the skull, copious effusion of blood, or severe concussion of the brain. Under such circumstances, the patient may die from shock, compression, or inflammation. The prognosis should, therefore, be guarded, especially as the degree of danger cannot always be estimated by the amount of visible injury. If the fracture is multiple, or the bones are crushed in, more or less deformity may be expected after the cure.

The *reduction* is generally easy. The patient being seated upon a chair, with his head reclining against the breast of an assistant, any depression that may exist is to be remedied by means of a female catheter or grooved director, inserted into the nostril, and made to bear against the displaced fragment until it resumes its proper level. Sometimes a good deal of pressure and counterpressure will be necessary, while at other times hardly any manipulation will be required, the mere passage of the finger over the seat of the fracture being sufficient to adjust the fragments. When the nasal septum, or perpendicular plate of the ethmoid bone, is thrown out of place, restoration may be effected by means of the finger, or some suitable instrument, introduced into the nostril.

When the fragments have a tendency to cave in, or to fall asunder, the best means of counteracting it is a stout adhesive strip, carried across the bridge of the nose from one cheek to the other; the plaster promptly adheres to the skin, and, assuming the shape of the nose, effectually prevents further displacement. Or, instead of this, the depressed fragments may be supported, as suggested by Dr. Lewis D. Mason, by means of a sharp, three-cornered, nickel-plated needle passed through the line of fracture, and retained with a lightly applied rubber band stretched across the bridge of the nose, and secured to the ends of the instrument. The older surgeons were in the habit in such cases of stuffing the nostrils with dossils of lint, smeared with ointment, and frequently changed for the sake of cleanliness. Subsequently, metallic tubes were recommended, and in modern times tubes of gum elastic have been used. All such contrivances are now very properly discarded; or, if they are ever employed, it is only in cases where it is impossible, from the manner in which the bones have been crushed, to remedy the displacement in any other way. During the whole of the after-treatment the patient should refrain from blowing his nose.

The symptoms which usually follow this accident, such as inflammation of the pituitary membrane, fetid discharge, and swelling of the nose and face, are combated by general and local bleeding, purgatives, and other antiphlogistics. The brain is carefully watched, and any untoward occurrence promptly met. Hemorrhage is restrained by cold applications, and elevation of the head and arms; if obstinate by plugging the nostrils, or by injections of a strong solution of subsulphate of iron. In neglected cases of this injury a not uncommon occurrence is deformity caused by the irregular projection of some of the fragments. In an instance of this kind, recently under my charge, the nose was restored to its natural form by rasping away the offending and superfluous matter with the aid of a dentist's engine.

FRACTURES OF THE NASAL CARTILAGES.

The nasal cartilages are sometimes broken, or broken and partially detached from the nasal and maxillary bones, the most common cause of the accident being a violent blow or fall, inflicting, perhaps, at the same time serious injury upon the soft parts. The nature of the case can seldom be mistaken. When the cartilages are displaced inwards, the nose will necessarily be more or less flattened and depressed, and the effects will assume increased importance, if the lesion be conjoined with fracture of the nasal bones and the cartilaginous septum. The treatment must be conducted upon general principles. The great aim should be to preserve the contour of the nose; hence, after having restored the parts to their proper relations, it may be necessary to plug the nostrils with

lint, well oiled, a metallic tube or piece of quill having previously been inserted to facilitate respiration. Leeches may be required to moderate inflammation.

In the case of a man, forty years of age, brought to the Clinic of the Jefferson Medical College, by Dr. McWhinney, the septum, broken into several pieces four months previously, encroached so much upon the left nostril as to cause almost complete obstruction to respiration on that side. In order to afford relief, I was compelled to cut away the whole of the offending part with a probe-pointed bistoury. The nose seemed to have been very little deformed by the accident.

Dr. Bolton, of Richmond, in a case of old displacement of the nasal septum, effected restoration by an ingenious process, consisting of a stellate incision made in such a manner as to form eight triangles with their apices converging to a common point. He then seized the triangles separately with a pair of forceps, and broke them at their base without detaching them. The comminuted part was next forced into its natural position and supported by appropriate dressings in the nostrils until union occurred.

FRACTURES OF THE UPPER JAW.

A fracture of the upper jaw implies the application of direct mechanical injury, in a concentrated and severe form. No ordinary force could produce such a result. In a few instances it has been caused by contre-coup, the head and lower jaw being wedged in between two hard, resisting bodies. Portions of the alveolar process, of variable shape, and even of large size, are sometimes broken off in the extraction of a tooth. There is nothing definite at all in regard to the situation of the fracture, since it may affect any portion of the bone, its body, ascending process, horizontal plate, or alveolar process. It is always accompanied by severe injury of the soft and hard parts, and is usually of easy recognition, simple inspection, or touch, commonly sufficing for the purpose. The accident is apt to be followed by violent inflammation, requiring prompt measures for its relief.

In the reduction, pressure and counterpressure are chiefly relied upon, the parts being moulded gently into their natural position by the fingers, either alone, or aided, as in fracture of the horizontal plate of the bone, by the grooved director inserted in the nostril. If the alveolar process has suffered, it may become necessary, in order to secure its proper maintenance, to tie together several of the contiguous teeth with thin silver wire. Whatever may be the nature of the case, the rule is, if possible, to save all, and take away nothing.

In 1865, I attended, along with the late Dr. Smiley, a man forty-seven years of age, who had broken the left upper jaw in falling head foremost from the third-story window of his house upon the cellar-door below, a distance of about thirty-five feet. He was much stunned by the blow, and it was not until after he had freely vomited, seven hours after the accident, that entire consciousness was restored. The face and forehead were greatly bruised and discolored, the nasal bones were comminuted, the left eye was ruptured, a considerable quantity of blood escaped from the nose and mouth, and the jaw was broken in such a manner that it could easily be moved about in different directions with the fingers. The line of fracture extended from behind forwards between the cuspid and small grinder, but none of the teeth were knocked out or even loosened. Notwithstanding the severity of the injury, the man rapidly recovered, with hardly any perceptible deformity, except what was caused by the state of the eye. For the first few weeks there was great difficulty in swallowing, and several months elapsed before solid food could be masticated. The treatment was very simple. Until the eighth day the principal remedies were anodynes, laxatives, and saturnine lotions. When the inflammation and swelling had measurably subsided, the head was carefully bandaged in such a manner as to keep the lower jaw in constant contact with the upper until the parts were thoroughly reunited.

FRACTURES OF THE MALAR BONE.

Fracture of the malar bone, as an uncomplicated lesion, is very uncommon. Like fracture of the upper jaw, it is always produced by direct violence, is invariably attended with severe contusion, if not with other injury of the soft parts, is, in general, readily recognized, is liable to be followed by high inflammation, and is easy or difficult of management according to the presence or absence of displacement. When the broken part is sunk down beyond its natural level, an attempt may be made to raise it, especially if there is already a wound denuding the bone, and admitting of the insertion of a suitable lever; if not, an incision is made, provided it seems probable that there will be unsightly

deformity after the cure, if the fragment be left in its abnormal situation. Such a procedure is much better than leaving the bone unreduced.

In fractures of the zygomatic arch of the malar and temporal bones, the fragments, as a rule, are forced backwards, and hence the deformity is sometimes very considerable, calling for reposition with an elevator. In a case recorded by Duverney, and in another mentioned by Packard, the displacement took place in a forward direction.

FRACTURES OF THE LOWER JAW.

The lower jaw bone may be broken in any portion of its extent, not excepting even the symphysis. Fracture here, however, is unusual, and is met with chiefly in young subjects, before the complete union of the two opposite halves of the bone. The most common site of fracture is the body of the maxilla, towards its anterior extremities, as in fig.

Fig. 448.
Fracture of the Jaw.

448, and next in point of frequency, at least according to my observation, its ascending ramus. The condyle, neck, and coronoid process are seldom broken. The fracture may be transverse, oblique, or longitudinal; single or multiple; simple or complicated. When the bone yields at two points, there will necessarily be three fragments, and cases occur in which the number is still greater, the bone being literally crushed. Thus, Houzelot has published the particulars of one in which the bone was broken, in a fall from a height, at both condyles, through both coronoid processes, and at the symphysis. Sometimes the lesion is limited to the alveolar process, or to this process and the body of the jaw. In either event, there will be involvement of the gums and teeth, with, perhaps, extensive separation, if not complete evulsion, of the latter. Occasionally, a longitudinal fracture of the body of the bone is intersected at each extremity by a transverse or an oblique one. The accident, which rarely occurs before the age of manhood, is much more frequent in males than in females. When the ends of the fragments are unusually long and sharp, they may, if the parts are not well supported, pierce the mucous membrane, thus converting a subcutaneous into an open fracture.

Direct violence, as a fall, blow, or kick, is the most common cause of fracture of the inferior jaw. In four instances, under my charge, it was produced by a blow with the fist upon the chin or side of the bone, one of the cases being a healthy lad, between fifteen and sixteen years of age; the others, persons between twenty-five and thirty-two. A very common cause of this fracture is the kick of a horse. Dentists often break off portions of the alveolar process in the effort to extract teeth. Sometimes frightful injury is produced in this way. Muscular action is capable of breaking the lower jaw. A man, upwards of seventy years of age, an out-patient at the College Clinic, presented himself to the late Professor Pancoast in January, 1857, on account of a fracture of the neck of this bone, caused the night before in a violent paroxysm of coughing. The symptoms were unmistakable. The explosion of powder in firing off a pistol within the mouth has also been known to give rise to the accident. Finally, the lower jaw is sometimes broken on one side from a blow upon the opposite, or by counterstroke, as in a case related by Dr. Cockburn, in which the bone yielded at its neck.

The *symptoms* of fracture of the body of the lower jaw are generally so well defined as to render it easy of diagnosis. Crepitation may almost always be detected by moving the fragments; and upon looking into the mouth the teeth will usually be found to have lost their natural relations. There is also commonly a perceptible inequality at the inferior border of the bone, which may readily be increased by motion, and which is of itself sufficient to point out the character of the injury. When the jaw gives way on both sides, the central piece is drawn downwards by the muscles of the throat, the front teeth are out of their normal position, and the mouth is open and distorted.

In fracture of the ramus there will be a grating noise at the site of the injury, and excessive pain near the ear. From the fact that the masseter muscle is attached to, and covers in, both fragments, there is seldom, if ever, any considerable displacement.

A fracture of the neck of the bone is easily detected, except in very fat subjects, by the crepitation produced on moving the jaw, by the preternatural mobility in front of

the ear, and by the manner in which the body of the bone is dragged forward by the action of the external pterygoid muscle. Similar symptoms characterize fracture of the condyle.

In addition to the symptoms now described as indicative of fracture of different portions of the inferior maxilla, there will be more or less impediment in speaking and swallowing, difficulty in opening and closing the mouth, and inability to masticate. The patient experiences severe pain at the seat of fracture, aggravated by motion and manipulation ; the soft parts are usually considerably contused, if not also lacerated ; and there is often smart hemorrhage, either from rupture of the mucous membrane or of the inferior dental artery.

Simple fractures usually unite in from four to five weeks, without ultimate deformity or functional impediment. Those of the neck of the bone require a longer time, and more care in their management, than those of the body and ramus. Complicated fractures of the jaw are often followed by severe suffering, caused either by inflammation, abscess, caries, or necrosis. Great emaciation sometimes arises from the inability of the patient to take sufficient nourishment during the long confinement of the parts.

During the *reduction* of these fractures, the patient should be seated upon a chair, with his head firmly supported upon the breast of an assistant. The surgeon, passing his fingers along the base of the jaw, supposing that it is the body that is broken, moulds the parts into proper shape, and then, closing the mouth, sees that the lower teeth rest fairly against the upper. When the fragments overlap each other, they must be drawn in opposite directions, when the slightest pressure will generally suffice to effect their restoration. If any of the teeth are loosened, or partially forced from their sockets, and they are perfectly sound, they should by all means be retained, being secured, if need be, to the adjacent ones, by a silver wire. Formerly it was the custom to treat all such teeth as extraneous bodies, under the erroneous belief that they were incapable of readhesion.

The fracture being reduced, as may always be known by the evenness of the dental arch and of the inferior margin of the jaw, a piece of pasteboard, or, what is preferable, of felt, fig. 449, immersed in hot water, is accurately moulded to the base and sides of the jaw, and, after being well lined with wadding, confined by a roller carried round the top of the head in the form of the figure 8, one portion of the bandage lying in front, the other behind the ears. The lower jaw being thus pressed firmly against the upper, the bandage is next conducted across the chin and the occiput above the ears, so as to give the fragments due support in front. This mode of dressing is very simple and efficient, and generally answers the purpose exceedingly well. When any unusual tendency to anterior displacement exists, it may readily be counteracted by a stout adhesive strip, extending from the chin along the lower part of the face to the side of the occiput. The annexed cuts, figs. 450 and 451, represent the bandages of Gibson and Barton, formerly so much

Fig. 449.	Fig. 450.	Fig. 451.
Felt Mould.   Gibson's Jaw Bandage.   Barton's Jaw Bandage.

employed in this country in the treatment of fractures of this bone. Instead of the felt or pasteboard splint, a mould of sheet lead may sometimes be advantageously used, as it readily adapts itself to the parts, and affords steady, uniform support. Recently I had under my charge a case of fracture of this bone, unattended with displacement, where a rapid and perfect cure was effected without any dressing whatever.

Professor Hamilton, in the treatment of fractures of this bone, employs an apparatus consisting of three straps, one of which, composed of firm leather, extends round the jaw

and head in the direction of the coronal suture, while the other two, made of strong linen webbing, pass horizontally round the head, above the ear, the anterior being buckled to the forepart, and the posterior to the backpart, of the vertical one. The great advantage of this contrivance, represented in fig. 452, is the strong support it gives to the ends of the fragments, thus effectually preventing displacement.

Instead of confining the splints or moulds used in the treatment of fractures of the lower jaw with the ordinary roller, a great point is gained by using the

Fig. 452.

Hamilton's Apparatus.

Fig. 453.
Thomas's mode of adjusting Fractures of the lower Jaw with wire and key.

immovable bandage, the hair previously been cut very close, and the head covered with a layer of wadding or thin flannel. Such a bandage, properly applied, keeps the parts effectually in position until complete union is obtained.

In fracture of the neck and condyle of the jaw, maintenance is always peculiarly difficult, on account of the action of the external pterygoid muscle. The most effective means of counteracting this tendency is to confine a thick, graduated compress behind the angle of the bone, the case being treated, in other respects, as if it were one of fracture of the body of the jaw.

In comminuted fracture, it is sometimes exceedingly difficult, if not impossible, despite the best directed efforts, to keep the fragments on a level with each other, such being their constant tendency to displacement. To rectify this tendency, the contiguous teeth should be connected together with delicate silver wire; or, what is better, because more efficient, some of the teeth may be secured to a thin silver plate, interposed between them and the checks. Mr. Tomes, of London, has suggested the use of a silver cap for the teeth, and Mr. Hugh O. Thomas, of Liverpool, connects the fragments together with silver wire, secured with a key, as in fig. 453. Mr. Hammond's ingenious contrivance also answers an excellent purpose. It consists of a frame of iron wire, fig. 454, which is slipped over the teeth, and fastened by passing around each a thin iron thread, as a

Fig. 454.

Hammond's Wire Splint for Fracture of the Jaw.

Fig. 455.
Hammond's Wire Splint applied.

binder, to keep the frame firmly in its place, as shown in fig. 455. The operation is completed by cutting off the ends of each thread, and turning them in between each two contiguous teeth, so as not to interfere with the movements of the lips and checks. Occasionally it is necessary to take a plaster cast of the jaw as a preliminary step.

The interdental splint, devised nearly at the same time by Dr. Gunning, of New York,

and by Dr. Bean, of Georgia, is adapted to fractures both of the upper and lower jaw, particularly to comminuted and compound fractures, attended with inordinate and constant tendency to displacement of the fragments. The only objections to its employment are, that it is somewhat expensive, and that it cannot always be readily obtained. The splint, as seen in fig. 456, consists essentially of a plate of vulcanized India-rubber, accurately moulded by means of a wax or plaster impression to the dental arches, and kept in position by a chin compress of the same material, fastened by an occipito-frontal bandage. In this way the most complete adjustment can be maintained without inconvenience to the patient, and, if the apparatus be properly constructed, without the slightest deformity, except in the event of great loss of bone. A good idea of the external parts of the apparatus is afforded by the annexed sketch, fig. 457.

Fig. 456.

Fig. 457.

Bean's Interdental Splint.

Interdental Splint, applied.

In edentulous subjects, a mould of hard rubber, constructed after the manner of the plate for artificial teeth, should be interposed between the two jaws. In no other way, in fact, can the ends of the fragments be maintained in apposition. Wedges of cork, recommended by some surgeons, are highly objectionable, as, from their porous character, they readily imbibe the secretions of the mouth, and thus become a source of fetor, if not of disease.

Wounds, contusions, and hemorrhage, complicating these fractures, are managed upon general principles; inflammation is combated by the usual measures; loosened teeth and necrosed bone are promptly removed; and the parts are kept steadily at rest, renewal of displacement being guarded against by the most sedulous attention both of the patient and the surgeon. The food should consist of slops, as grated cracker and milk, broths, gruel, beef essence, and similar articles, introduced into the mouth with a small spoon. The custom which formerly prevailed of conveying nourishment into the stomach by means of a tube passed through the nose, has become obsolete, as well as the still more reprehensible practice of extracting one of the front teeth, to afford room for feeding the patient. After the case has advanced for several weeks, a semisolid, farinaceous diet may be allowed.

In compound and comminuted fractures of the lower jaw, especially in those caused by gunshot injury, the secretions of the mouth and of the salivary glands are always excessively foul and abundant, and are liable, if swallowed, to give rise to a low, typhoid condition of the system; in fact, to a bad form of septicemia, followed gradually, if not soon relieved, by death. In order to prevent such an occurrence, the greatest attention should be paid to cleanliness, the mouth being frequently washed with lotions of chlorinated sodium, alcohol, or permanganate of potassium, abscesses promptly opened, dead bone removed, and the strength supported with quinine, iron, opium, and alcoholic stimulants.

An instance of ununited fracture of this bone is sometimes met with, and now and then a false joint is found to exist, requiring, in the former case, the employment of ordinary measures, and in the latter, denudation of the ends of the fragments, aided, perhaps, by the silver wire suture or the insertion of a metallic pin.

FRACTURES OF THE HYOID BONE.

The hyoid bone, from its great mobility, and from the protection which it receives from the lower jaw, is seldom the seat of fracture. The accident is usually occasioned by falls or blows, or by the pressure of the thumb and fingers in attempts at strangulation. An instance is mentioned where it was produced by muscular action, the patient having fallen violently backwards upon his head. Persons who commit suicide by hanging occasionally break this bone with the rope. The fracture is generally seated in the large horns, sometimes in both, at other times only in one. It is liable to be complicated with injury of the larynx, lower jaw, and other parts, the skin being usually bruised and discolored. The patient is unable to swallow, to articulate distinctly, and to move his tongue, except in the most limited degree, and then not without great suffering, and, perhaps, a sense of suffocation. Crepitation is generally sufficiently evident, especially during deglutition and when the index finger is placed upon the throat in contact with the smaller fragment, the corresponding finger resting upon the neck. The pain is very acute, and is aggravated by the slightest motion. Sometimes the patient is conscious of a peculiar crushing sound at the moment of the accident. Occasionally there is laceration of the mucous membrane of the fauces, followed by copious hemorrhage, as in a case reported by Professor Wood, of Cincinnati.

Fracture of the hyoid bone, although not in itself necessarily dangerous to life, often becomes so in consequence of its complications, death having occurred in 12 cases out of 23 referred to by Fischer, of Hanover. Even in the most simple cases it is generally exceedingly troublesome, on account of the great mobility of the fragments, and the severity of the supervening inflammation and swelling. Occasionally abscesses form, the detached piece becomes necrosed, and the neck is pierced with fistulous orifices, which are slow in healing. The accident has hitherto been noticed chiefly in aged subjects, probably on account of the great brittleness of the bone at that period of life.

In the treatment of this fracture, the head must be inclined forward, and maintained in a state of the utmost quietude, by an appropriate bandage secured around the chest. If there is much displacement, readjustment should be attempted by means of the finger in the throat while counterpressure is made externally. Perfect silence should be enjoined. Pain and swelling are subdued by leeches applied to the neck, followed by saturnine and anodyne fomentations ; the bowels are freely evacuated by stimulating injections, and fever is combated by the usual means. For the first few days, the amount of food and drink should be barely sufficient to sustain life. If the patient cannot swallow, the stomach tube must be used, or nourishment must be administered by the rectum. After the swelling of the neck has measurably subsided, an attempt should be made to keep the fragments in place by compresses and adhesive strips. If necrosis occur, the dead bone should be promptly extracted. In ordinary cases, the fracture will unite in from six to eight weeks.

FRACTURES OF THE CLAVICLE.

The clavicle, owing to the delicacy of its structure, its exposed situation at the top of the chest, and its connection with the shoulder and arm, is extremely liable to break. Of 2358 cases of fractures of different pieces of the skeleton, referred to by Malgaigne, 228 occurred in this bone, and of this number nearly three-fourths were observed in the male, thus exhibiting a remarkable disparity in regard to the relative frequency of the lesion in the two sexes. The accident is not peculiar to any particular period of life ; I have witnessed it in a child under six months of age ; and Dr. W. Keller, formerly of this city, showed me a case in which it had taken place in the fœtus from the fall of the mother upon the wheel of a carriage, at the eighteenth week of gestation. The child, at the time of my examination, was several months old, and the seat of the fracture, which was near the middle of the right clavicle, was indicated by a well-marked forward angular projection of the ends of the fragments, which, however, were firmly united before birth. A similar case was shown to me, in 1861, by Dr. William B. Atkinson, the fracture having been produced by a blow upon the abdomen of the mother at the end of the seventh month of pregnancy. Gurlt has collected the particulars of seven cases of intrauterine fracture of this bone caused by external violence.

Fractures of this bone may be simple, compound, or comminuted ; unilateral or bilateral ; transverse or oblique ; partial or complete. A strictly transverse fracture of the clavicle is among the rarest of accidents, and I have myself never met with an instance

of it, either in the living subject, or in any of the specimens contained in our museums. The bone nearly always gives way obliquely, the ends of the fragments being generally rather long and sharp, and often distinctly serrated. When very sharp, they may pierce the skin, or, at any rate, press against it with so much force as to cause much uneasiness, and not a little difficulty in maintaining apposition. It is very uncommon for the bone to break at several points; such an accident, in fact, can only happen from the application of direct injury. Simultaneous fracture of both clavicles is exceedingly rare. I have two clavicles in my possession, from the same subject, which were broken in the same situation, but whether by the same accident, I am unable to say. Only six instances of the double injury are referred to by Malgaigne. To these may now be added three others, recorded, respectively, by Foucher, Rhoads, and Burr. Of 158 cases of fractures of the clavicle treated in the New York Hospital, 4 were double. The incomplete fracture of this bone is an accident of early childhood, and is of much more frequent occurrence than is generally supposed.

The seat of the fracture is usually at or near the middle of the bone, as it is here that it is thinnest and weakest. Of twelve preparations now before me, it is about this point in eight; in three it is towards the acromial extremity, and in one towards the sternal. Fracture of either end is very uncommon, and I have never met with an instance, either during life or after death.

Great displacement, as shown in fig. 458, generally attends fractures of the clavicle; now and then, however, the broken ends maintain their natural relations, as I have myself noticed in five instances. Such an event can only occur when the fracture is incomplete,

Fig. 458.

Fracture of the Clavicle.

or when the periosteum is only partially divided and there has been no dragging of the shoulder. Generally the outer fragment is drawn downwards, forwards, and inwards, by the weight of the limb and by the action of the deltoid, pectoral, and subclavian muscles; the inner, on the contrary, is usually somewhat raised by the sterno-cleido-mastoid, but not so much as its extraordinary prominence would seem to indicate, its tendency to displacement in that direction being pretty effectually counteracted by the great pectoral muscle and the costo-clavicular ligament. These appearances are well seen in fig. 459. Cases in which the acromial fragment overlaps the sternal, although infrequent, have been witnessed by numerous observers, as Desault, Malgaigne, Guéretin, Syme, Hamilton, and Stephen Smith. In fracture of the extremities of the clavicle, the loss of apposition is usually very slight, owing to the manner in which the bone is attached to the scapula and the sternum. In comminuted fracture, the displacement may be so great as to render reposition impracticable, the middle fragment being occasionally tilted up perpendicularly. When the bone gives way external to the coraco-acromial ligaments, the outer fragment is sometimes turned round at a right angle with the inner.

Fig. 459.

Complete Oblique Fracture near the Middle of the Clavicle.

The accident is generally caused by indirect violence, as a fall upon the hand, elbow, or shoulder, especially the latter, in which the sternal extremity of the bone is impelled by the weight of the body, at the same time that the acromial end is thrust forcibly in the opposite direction by the object struck against. Not unfrequently, however, it occurs from direct injury, as a blow or fall. I have seen two cases in which it was occasioned by the recoil of a shot-gun; and a similar example was reported to me by the late Dr. Herschel Foote, of West Philadelphia. Children often break the clavicle by tumbling out of bed, or by rolling down a flight of stairs. In several instances, as in one recently reported by Dr. W. E. Whitehead, of the Navy, the accident was caused by the inordinate action of the pectoral and deltoid muscles. Gurlt has collected the particulars of twenty cases of fracture of the clavicle produced by muscular contraction. In a case observed by Dr. Willard Parker, it was produced in an effort to strike a dog with a whip, the bone

being slightly diseased at the time. When both clavicles are broken, one generally gives way by indirect, and the other, immediately after, by direct force.

The *symptoms* are generally well marked. The shoulder has a singularly depressed appearance, being drawn downwards, forwards, and inwards by the weight of the limb and the action of the muscles, especially the deltoid and small pectoral ; the head and trunk are inclined towards the injured side ; there is impossibility of rotating the arm, or of carrying the hand to the face ; and the patient commonly supports the elbow in order to take off the weight of the limb from the broken bone. The seat of the fracture is generally readily discovered by the eye, the deformity being nearly always extremely conspicuous ; and the finger, as it traces the outline of the bone, cannot fail to detect any existing irregularity. Crepitation is elicited by taking hold of the elbow and pushing the arm upwards, outwards, and backwards, in a direction opposite to that of the displacement. The same procedure will serve to efface the deformity, which, however, is instantly reproduced upon the removal of the restraint. When the fracture is imperfect, serrated, or unattended with displacement, there is usually an absence of crepitation, and the diagnosis can be established only, as a general rule, by a careful digital examination, aided by the alternate elevation and depression of the shoulder. In such a case the plan suggested by Roberts is worthy of trial. The patient is desired to raise himself upon his two wrists, and, while he does this, the fingers applied to the clavicle readily detect crepitation.

Although the patient is generally unable, in fracture of the clavicle, to carry his hand to the head, I have met with some very striking exceptions to this rule, both in children and adults. In a man, forty years of age, whom I saw with Dr. O'Reilly, this movement could be executed with quite as much facility as with the other limb. He could even swing the limb about without any pain or inconvenience. The fracture, caused by a fall upon the edge of a doorstep, was situated towards the acromial extremity of the bone, and was attended with marked displacement. In children, this anomaly is much more frequent than in grown persons.

Fractures of the clavicle are, according to my experience, seldom cured without more or less deformity, whatever pains may be taken to prevent it. In some of my cases I have found it impossible, despite the greatest care and patience, to effect accurate restoration ; but even when the parts are placed in the closest relations with each other, the slightest movement of the head, neck, trunk, or arm is often sufficient to separate them. This difficulty will, I think, be most likely to occur when the fracture is situated at or towards the acromial extremity of the bone, in which the outer fragment is frequently, if not generally, thrown backwards in such a manner as to render it almost impossible to bring it to its natural position. From the cases that I have seen of this fracture, as treated by other surgeons, and from the numerous specimens of it to be found in our museums, it is certain that a cure without deformity is very uncommon. It is gratifying, however, to know that the deformity, even if considerable, does not generally at all impair the usefulness of the limb. Union will, of course, be materially retarded, but in time nature will succeed in rounding off the ends of the fragments, and in connecting them firmly together, either by an osseous clasp or by a kind of bridge. When union fails to occur, the power of the arm is always weakened. In some cases a false joint is formed, and the ends of the fragments move more or less freely upon each other. Consolidation ordinarily takes place, in the adult, in about five weeks ; in children, in eighteen to twenty days.

Among the more serious effects of fracture of this bone are, violent inflammation of the soft parts, followed by erysipelas, suppuration, and great swelling ; extensive extravasation of blood, with consequent discoloration of the skin ; and paralysis of the arm from concussion, contusion, or compression of the axillary plexus of nerves. These occurrences, especially the latter, are most frequent in compound, comminuted fractures of the clavicle, attended with inordinate displacement of the fragments. A few examples of gangrene of the superior extremity from compression of the subclavian vein have been recorded, and the subclavian artery has occasionally been lacerated. Annoying abscesses sometimes form, and in all compound injuries of this bone, erysipelas is a common occurrence. Gunshot fractures of this bone are often very serious accidents, from the injury inflicted upon the soft parts around both by the bullet and the osseous splinters, which are sometimes scattered about in every direction. Partial paralysis of the superior extremity, with atrophy and permanent contraction of some of the muscles of the arm, forearm, and hand, may be mentioned as an occasional result of these lesions, as in a case recently under my observation in a lad, fifteen years of age, who had the right collar-bone badly broken four months and a half previously by the recoil of a shot-gun.

The *reduction* is generally easily effected by grasping the elbow and carrying the arm upwards, outwards, and backwards. If anything further be required, the fingers may be passed along the broken bone, to mould the ends of the fragments into proper shape. To maintain the parts in this position, the elbow should be permanently secured to the anterior and lateral aspect of the chest, the forearm lying across the front in such a manner as to make the hand grasp the sound shoulder, where it should remain during the whole of the after-treatment. Of the numerous contrivances that have been devised as retentive means in fractures of this bone, I give the most decided preference to that depicted in fig. 460, known as Velpeau's dressing, consisting of a wedge-shaped pad and an ordinary muslin roller, carried around the limb, shoulder, and chest, so as to secure the parts firmly in the position above indicated. The pad should rest in the axilla, with the large end uppermost, and should be well secured to the opposite shoulder by broad tapes. As a preliminary step, the trunk should be incased in a layer of wadding to protect the skin. The different turns of the bandage should be thoroughly wet with a saturated solution of silicate of potassium, applied with a suitable brush, and thus kept permanently in place, the whole forming an immovable dressing, which, unless the weather is very hot, or the skin unusually perspirable, may be worn comfortably without being changed, until the fracture is completely consolidated. If any of the turns of the bandage become loose, they may easily be glued together with the silicate, thus obviating the necessity of renewing the entire dressing.

Fig. 460.

Velpeau's Clavicle Bandage.

The adhesive plaster dressing which I introduced to the notice of the profession in 1852, and which I at one time employed a great deal in the treatment of fractures of the collar-bone, is, when properly applied, not only very efficient, but neat and comfortable, easily renewed, and particularly adapted to children. The strips, which should be from two to three inches in width, may be so arranged as to make a certain degree of pressure, through the medium of a compress, directly upon the seat of the fracture; or, if this be deemed unnecessary, the seat of the fracture may be kept under constant surveillance by letting it remain uncovered. The dressing need not be renewed oftener than once or twice, if, indeed, at all, during the entire treatment. If the skin be covered with hair, the surface should previously be well shaved, to facilitate the removal of the plaster. Any tendency in the shoulder to sink forwards and inwards should be counteracted by means of an axillary pad.

The apparatus of Dr. Fox, for the treatment of fractures of the clavicle, has become classical with the profession of this country, having been in general use for upwards of thirty-five years. At the Pennsylvania Hospital, where it was originally introduced, hardly anything else was, until recently, employed for this purpose. It is composed, as seen in fig. 461, of an axillary pad, of a sling for the forearm and elbow, and a well-stuffed muslin ring to encircle the sound shoulder, and receive the tapes attached to the ends of the sling. An additional support for the hand is suspended from the neck. The apparatus of Dr. Fox has been highly lauded, on the ground that it perfectly fulfils all the indications of treatment. I have not, however, found it at all equal to either of the contrivances above described. Its great defect consists in its allowing too much freedom of motion of the arm, thereby endangering displacement of the ends of the fragments; and a similar remark is applicable to the various modifications of this apparatus by Levis, Hamilton, Bartlett, and other surgeons. The great desideratum is to keep the arm, forearm, and hand immovably fixed, otherwise accurate maintenance of the fractured extremities will be impossible. Hence, in the employment of these contrivances the arm should always be well bandaged to the trunk. An axillary pad I use only when there is a strong tendency in the shoulder to sink downwards and inwards. In all other cases it may very properly be dispensed with, the more especially as its employment, if not carefully watched, may produce undue compression of the axillary vessels and nerves, terminating, as it has occasionally done, in inflammation, ulceration, gangrene, or partial paralysis of the corresponding limb. An instance has been reported in which, from this cause, the brachial artery was obliterated.

The stellate or figure-of-8 bandage was at one time a great favorite with French surgeons in the treatment of this injury, and there is no doubt that many excellent cures

Fig. 461.

Fox's Apparatus for Fracture of the Clavicle.

Fig. 462.
Figure-of-8 Bandage.

were effected with it. It consists, as shown in fig. 462, of a wedge-shaped pad and a long roller, carried alternately around each shoulder, after which the arm and forearm are

Fig. 463.

Boyer's Apparatus.

secured to the side and front of the chest in the usual manner. The bandage of Desault, once so much employed in this country, has become obsolete. Boyer's apparatus for fracture of the clavicle is represented in fig. 463, and is a very neat and efficient contrivance.
Dr. Moore, of Rochester, prefers to all other contrivances in the treatment of these fractures what he terms the " elbow figure-of-8 bandage," consisting of a piece of cotton cloth, two yards long, and, when folded like a cravat, eight inches in breadth at the middle. The object of this arrangement is to form a sling for the elbow and to carry the arm backward in close contact with the side of the chest, so as to maintain the clavicular portion of the great pectoral muscle in a state of tension. The centre of the bandage resting on the elbow, the posterior tail is carried by a spiral movement across the front of the shoulder of the affected side, and intrusted to an assistant; the other end is then carried across the forearm, raised at an acute angle with the arm, behind the back, over the opposite shoulder, and around the axilla, where the extremities are firmly stitched or pinned together. The forearm is suspended by a broad strip of muslin to the top of the main bandage, the hand being left free. The adjoining cuts, figs. 464 and 465, afford a good view of the arrangement of Moore's dressing.

Dr. Dugas, of Georgia, in fractures of this bone, simply employs a triangular piece of thick, unbleached muslin, to each angle of which is attached a bandage from three to four yards in length by three inches in width. The apparatus, which is described at length in the Southern Medical and Surgical Journal for 1852, is applied in such a manner as to form a sling for the elbow and forearm, at the same time that the arm is firmly secured to the side. No pad is used.

In children the most simple management frequently suffices, in the treatment of this

lesion, especially when the fracture is incomplete, the ends of the fragments remaining partially in apposition. In such a case all that is really necessary is to suspend the forearm and elbow in a sling, and to confine the arm to the chest with a few broad strips of adhesive plaster. In the treatment of fractures of the collar-bone in women special care must be taken in the application of the bandages not to injure the breasts.

Fig. 464.
Fig. 465.
Moore's Apparatus for Fracture of the Clavicle. Front view.

Moore's Apparatus. Back view.

Great stress is very properly laid by surgeons in the treatment of fractures of the collarbone since attention was first prominently directed to the subject by Dr. Edward Hartshorne, of this city, upon the employment of the supine posture, the special efficacy of the plan depending largely upon the pressure made upon the lower angle of the scapula. In order to render the treatment as efficient as possible, the patient's back should rest upon a broad, firm, unyielding mattress, the head should be raised and slightly inclined forwards to relax the sterno-cleido-mastoid muscles, and the forearm and elbow should be supported in a sling across the chest, the palm of the hand grasping the shoulder. To assist in pressing the shoulder backward it has been suggested to keep it covered for the first few weeks with a bag of shot weighing six or eight pounds. The great objection to this mode of management is that it necessitates a long and tedious confinement in bed, which few persons are willing to undergo. Women ought to be more willing than men to submit to it, inasmuch as the avoidance of deformity in them is of much greater importance.

Von Langenbeck, in view of the great difficulty of keeping the ends of the fragments in contact in fractures of this bone, has of late employed the wire suture, and he warmly recommends the general adoption of this measure. Such a procedure, however, is not only difficult, but few cases can arise in which it can be necessary or proper.

When both clavicles are simultaneously fractured, the treatment should be conducted upon the same general principles as when one alone of these bones is broken. Two small axillary pads will generally be required to keep the shoulders properly in place, and the elbows should be raised with more than ordinary care. Confinement of the patient in bed for several weeks will materially conduce to his comfort and rapid recovery. The treatment will be greatly facilitated under such circumstances, by the use of the figure-of-8 bandage, or Boyer's apparatus in keeping the fragments in place.

In comminuted fracture of the clavicle attended with compression of the subclavian vein threatening gangrene of the superior extremity, the only rational procedure is speedy removal of the offending fragment, provided reposition by the ordinary means is unavailing. A compound fracture, in such a case, would be far preferable to the risk of loss of limb and life. Laceration of the subclavian artery, consequent upon comminuted fracture of this bone, must be treated with the ligature, the vessel being tied at both ends.

An ununited fracture of this bone is an unfortunate occurrence, especially when it is caused by great loss of substance, as it is then irremediable. In ordinary cases a seton, cautiously inserted, will answer the purpose; or the ends of the fragments might be connected together with a steel screw, or silver wire.

FRACTURES OF THE SCAPULA.

Fractures of the scapula are extremely uncommon. Of 1902 cases of fractures of different pieces of the skeleton, treated at the Middlesex Hospital, London, only 18, according to Lonsdale, occurred in the shoulder-blade. At the Hotel-Dieu, at Paris, the scapula, in 2358 cases, was broken only in 4. On the contrary, a remarkable disproportion of such cases sometimes occurs in the hands of particular surgeons. Thus, Dr. Dugas has met with four cases of this accident, and Dr. Bullock with not less than six, although neither has witnessed an unusual number of other fractures. The injury may show itself in various forms and directions, and may occupy either of the two processes of the scapula, its neck, its body, or its inferior angle.

α. The *acromion process*, fig. 466, from its exposed situation, is more frequently broken than any other part of the bone, the accident being usually caused by a blow upon the

Fig. 466.

Fracture of the Acromion
Process.

top of the shoulder, or by violence applied directly to the process itself. It may also be produced by force transmitted along the humerus by a fall upon the elbow or the palm of the hand. In a case treated by Mr. Phillips, of London, the accident was the result of muscular contraction. There is reason to believe that what is sometimes regarded as a fracture of this process is merely a separation of its epiphysis, which frequently fails to coalesce with the rest of the bone until late in life, as I have seen in a number of examples. The osseous consolidation is occasionally postponed until after the age of forty. The fracture is generally somewhat oblique, and its signs are so peculiar as to be characteristic. The natural rotundity of the shoulder is destroyed; the outer fragment is drawn down by the weight of the arm, which hangs motionless by the side of the body; the head of the humerus can be felt in the axilla; there is a depression at the situation of the fracture; the distance between the shoulder and the top of the sternum is diminished; and crepitation may be detected on lifting the arm in contact with the displaced fragment. In addition to these symptoms there is acute pain at the seat of the injury; the limb cannot be raised by its own efforts; and the patient inclines his head towards the affected side, and supports the forearm as in fracture of the clavicle.

The only accident with which fracture of the acromion process is liable to be confounded is dislocation of the humerus, from which, however, it may generally be easily distinguished by the sunken appearance of the shoulder, the mobility of the outer fragment, the existence of crepitation, and the ready effacement of deformity by the elevation of the arm, followed by its instantaneous recurrence when the surgeon relinquishes his hold. In dislocation, the acromion process stands out in bold relief, crepitation is absent, and the head of the humerus is firmly fixed in its abnormal position.

The union is usually ligamentous instead of osseous, owing to the difficulty experienced in preserving the contact of the fragments. This occurrence will be more likely to happen when the tip of the acromion is broken off than when the fracture is seated near its root.

In the treatment of this accident the leading indications are to secure the arm and forearm firmly to the antero-lateral part of the chest, and to raise the humerus against the top of the shoulder-joint, so that its head may serve as a splint for the broken process. For this purpose, the same bandage is used as for fracture of the clavicle, but the axillary pad is dispensed with, lest the broken piece should be pushed too far outwards.

β. In fracture of the *neck* of the scapula, fig. 467, the coracoid process and glenoid cavity are detached from the rest of the bone in an oblique direction. The accident is one of such great rarity that many surgeons have doubted the possibility of its occurrence. It can be produced only by great direct violence, although one case—that of Mr. May, of England—is known in which it was caused by muscular contraction in a young lady, in the act of throwing her necklace over her shoulder, the bone having doubtless been exceedingly brittle from some organic defect.

The symptoms are always well marked. The acromion is unusually prominent, the head of the humerus is felt in the axilla, the shoulder has a flattened appearance, the limb is lengthened, the coracoid process is thrown down below the clavicle, between the deltoid and pectoral muscles, severe pain and numbness are experienced in the axilla, and distinct crepitation is perceived on rotating the arm upon the scapula. The accident bears, at first sight, considerable resemblance to a dislocation of the humerus into the axilla, from which, however, it may always be readily distinguished by the facility with which the parts may be restored to their natural situation, by the immediate return of the symptoms when the limb is left to itself, and by the existence of crepitation. From fracture of the neck of the humerus it may be known by the circumstance that, in the latter, the shoulder retains its rotundity, and that the limb, instead of being lengthened, is shortened ; the acromion also is much less prominent.

Fig. 467.

Fracture of the Neck of the Scapula.

In two cases of this accident, observed by Dr. Dugas, the fracture, produced by a blow upon the shoulder from a falling tree, was instantly followed by paralysis of the limb and cessation of pulsation in all its arterial trunks ; a consequence, evidently, of injury done to the axillary nerves and vessels. Treatment having been neglected, no union took place, and the arms never recovered their functions.

This fracture is retained with difficulty, and is liable to be followed by stiffness of the shoulder-joint, atrophy and paralysis of the muscles of the arm, and other disagreeable effects. It is managed in the same manner as fracture of the clavicle, with an axillary pad, the elbow being kept well raised, and the scapula thoroughly steadied until there is complete reunion. If the parts are much contused, leeches, fomentations, and other antiphlogistics may be required. Passive motion should be instituted at the end of four weeks, and afterwards renewed every few days. Consolidation may be expected in two months.

It is not improbable that the edges of the glenoid cavity may occasionally be broken off, either by direct force, or by the sudden and violent propulsion of the head of the humerus. It is remarkable, however, that the existence of such a lesion has never been demonstrated by dissection. Is it not likely that some of the bad forms of luxation of the shoulder-joint, in which the reduction is maintained with great difficulty, and which are so liable to terminate in permanent ankylosis and ruin of the articulation, are cases of this description ? The subject is worthy of greater attention than it has hitherto received.

Fig. 468.

Fracture of the Glenoid Cavity.

Fig. 469.

Fracture of the Coracoid Process.

In the annexed cut, fig. 468, from Fergusson, the fracture extends through the glenoid cavity.

γ. The *coracoid process* is sometimes broken by a severe fall or blow, generally a short distance from its tip, the fracture being usually accompanied by great contusion of the soft parts, and fracture of the acromion, clavicle, or humerus. The accident, which is of very rare occurrence, is characterized by inability to raise and adduct the arm, by preternatural mobility, by depression of the detached fragment by the conjoined action of the small pectoral, two-headed flexor, and coraco-

brachial muscles, and by the detection of crepitation on moving the arm upon the shoulder, the finger being placed between the deltoid and great pectoral muscles. The adjoining sketch, fig. 469, from a preparation in Professor Neill's collection, affords an illustration of a well-marked specimen of fracture of the coracoid process.

The treatment consists in confining the arm and forearm to the anterior part of the chest by means of a bandage and sling, similar to those used in fracture of the clavicle, care being taken to keep the elbow well raised, so as to fix the top of the scapula, and support the broken part. By this proceeding, the pectoral and flexor muscles of the arm are relaxed, and prevented from acting injuriously upon the tip of the coracoid process.

Violent inflammation, occasionally terminating in profuse suppuration, and even in death, is liable to follow this accident, from injury inflicted upon the pectoral muscles and

Fig. 470.

The ordinary Situations of Fracture of the Body of the Scapula.

the axillary vessels, nerves, and glands. The matter, being deep-seated, experiences great difficulty in reaching the surface, and is, therefore, disposed to burrow extensively among the surrounding structures. The proper remedy is an early and free incision at the most dependent portion of the abscess.

δ. The *body* of this bone, fig. 470, rarely suffers from fracture, and then only from great direct violence, causing at the same time serious injury in the soft parts. In one case, recorded by a foreign writer, the accident is said to have been produced by muscular action. The fracture exhibits no regularity in regard to shape, is often multiple, and is rarely attended with displacement.

Fracture of the body of this bone occasionally extends through its spine, so as to divide it into two nearly equal vertical parts, as in a case which I attended with Dr. Rohrer. The patient was a strong laboring man, thirty-seven years of age, who, in a fall from a scaffold, struck his right shoulder violently against the corner of a plank, fracturing the scapula through the spine and body near its centre. Five days had elapsed before I saw him. The parts were then much swollen and ecchymosed, the top of the shoulder was depressed and forced forwards, and there was a marked irregularity between the ends of the fragments, the outer being drawn downwards and forwards, so as to form with the posterior a kind of triangle, thus ⎯⎯⎯⎯ , with distinct crepitation upon the slightest motion. The man, who experienced great pain at the time of the accident, was unable to put his hand to his head, but could easily touch the opposite shoulder.

To steady the shoulder-blade, which is the leading indication in the treatment of this accident, two large, narrow, and moderately thick compresses should be placed along its axillary and vertebral borders, and confined by a broad roller carried round the upper part of the trunk; or, instead of this, they may be secured by means of large adhesive strips. The arm and forearm are fastened to the anterior part of the chest, as in fracture of the clavicle. In the case above described, apposition was easily maintained by a modification of Desault's apparatus.

ε. Fracture of the *inferior angle* of this bone is marked by preternatural mobility, by displacement of the smaller fragment by the action of the great serrated muscle, and by acute pain at the seat of the injury. The diagnosis may readily be established by fixing the top of the scapula and moving the lower angle; if they follow each other, it will be an evidence that there is no fracture, and conversely. The treatment is the same as in fracture of the body of the bone.

FRACTURES OF THE RIBS.

The central ribs, from their exposed and fixed position, are much more liable to be broken than the upper and lower; the former being safely protected by the collar-bone, the scapula, and numerous thick and strong muscles, while the latter, from their great shortness and mobility, can readily glide out of the way of any injury that might otherwise affect their integrity. However this may be, they usually yield at their more prominent points, in an oblique direction, a transverse fracture being here, as elsewhere, an unusual occurrence. A denticulated or serrated appearance of the ends of the fragments is occasionally met with, and now and then, although rarely, they are impacted, or driven

into each other.   The accident is most frequent in elderly subjects, children and young persons seldom suffering.   The causes are twofold, external violence and inordinate muscular action.   The first produces its effect either in a direct or indirect manner; most commonly in the former, as when the ribs are struck by a fall or a blow, or when the body is traversed by the wheel of a carriage.   In the second case, the ribs, being impelled by forces operating upon their extremities, break at or near their middle, as when, for example, the back of the chest is pressed against a wall by a railway car.   When these pieces are acted upon directly, their curvature is diminished, but increased when the violence is applied indirectly.   I recently attended a lady, seventy-four years old, who had the eleventh rib of the left side fractured by her granddaughter, a stout girl of fourteen, by throwing her arms around the body, in a friendly embrace, on going to bed.   In 1837 a number of persons met with severe injuries of this kind, by being severely squeezed in a crowd in the Champs de Mars, at Paris.   A rib has occasionally been broken by mere muscular contraction in the act of coughing, sneezing, or slipping, as in a case reported by Dr. Groninger; but such an occurrence is unusual, and generally implies an abnormal condition of the osseous tissue.

Fractures of the ribs are said to be common among insane persons, but whether they occur spontaneously or as the result of accidental causes is not determined.   In many of the reported cases they did not seem to have been productive of pain or to have been accompanied by the usual phenomena, not even by any evidence of contusion or discoloration of the skin.

The number of ribs broken at any one time is variable.   The largest number I have ever met with was eight; sometimes, however, it is still greater.   In a specimen in my collection, from the body of a woman, upwards of seventy years of age, who threw herself out of a second-story window, there are not less than fifty-nine fractures, twenty-seven on the right side and thirty-two on the left.

The fracture may occur simultaneously upon both sides, as in the case just mentioned; and it may be either simple, or complicated with other injury, as rupture of the intercostal artery, wound of the soft parts, and laceration of the pleura and lung.

A fracture of the more superficial ribs is often easily detected simply by placing the hand upon the part where the violence is supposed to have been inflicted, and requesting the patient to cough.   The bones being thus obliged to undergo a sudden motion, the lesion, if any exist, will almost be sure to manifest itself by the occurrence of crepitation and preternatural mobility.   If, however, the fracture is placed under cover of a large quantity of muscular and fatty matter, as in certain situations in robust and corpulent subjects, it may be very difficult, if not impossible, to discover it.   In such an event, the examination should be repeated again and again, until the diagnosis is satisfactorily determined.   The difficulty will be increased if only one rib is broken, or if the broken bone retains its normal position; on the other hand, the diagnosis may be established at a glance if the injury is extensive, and attended with marked displacement, as when it has been inflicted by a fall, or by the kick of a horse.   Finally, the patient, as he takes a deep inspiration, is occasionally sensible of a peculiar cracking noise at the site of the fracture.

The pain attending the fracture of a rib is generally very acute, and is always most severe at the seat of the injury; it is aggravated by the respiratory movements, and is commonly so excessive as to compel the patient to breathe entirely with the diaphragm. Every attempt at a full inspiration, coughing, or sneezing, is followed by exquisite suffering.   In very violent cases, the pain resembles that of pleurisy, and is accompanied with intense thoracic oppression.   If the lung has been wounded by a spicule of bone, or the projecting end of the broken rib, there will probably be spitting of blood, if not hemoptysis, and, perhaps, also emphysema.   In the latter event, the air may fill the cavity of the chest, causing a hollow, drum-like sound on percussion, and total extinction of the respiratory murmur, attended with great increase of dyspnoea.   Sometimes, as in injury of the costal and pulmonary pleura, the air escapes into the subcutaneous connective tissue forming a diffused tumor, soft and crackling, and at once indicative of the nature of the case. More or less copious hemorrhage will be present when there is laceration of an intercostal artery, the blood occasionally passing into the chest, but more generally escaping externally.

The ribs being firmly connected to the costal cartilages in front, and to the vertebræ behind, it is impossible for them to undergo any shortening when they are fractured, or for the ends of the fragments to overlap each other, at least to any extent, as in fracture of the long bones.   Derangement, however, may take place in almost any other direction, although the angular displacement is by far the most common, and this may be either

outwards, as in fig. 471, or inwards, as in fig. 472, according to the manner in which the injury was inflicted, the latter being usually produced by direct violence, the former by indirect. It is seldom, however, that more than one end of the bone is displaced in this direction at the same time. The Mütter cabinet contains several specimens in which one of the fragments projects above the level of the others.

Fig. 471.
Angular Displacement Outwards.

Fractures of the ribs are not always devoid of danger, even when they are perfectly simple, or apparently free from complications. Their number may be so great as to occasion severe shock, or such an amount of local and constitutional disturbance as to cause alarming illness and even death. The danger is generally greater, other things

Fig. 472.
Angular Displacement Inwards.

being equal, in fracture of the upper ribs than in fracture of the middle and lower, because a greater degree of violence is generally required to produce it. A fracture complicated with injury of the lung and pleura must be looked upon as a serious occurrence, as it is sure to be followed by more or less inflammation, if not by hemorrhage and pneumothorax. An escape of air beneath the skin is a matter of no consequence, except as indicating serious lesion within the chest. Hemorrhage from a wound of an intercostal artery is usually rather troublesome than dangerous.

A case, under my observation in 1854, strikingly illustrates the danger of fracture involving a number of these bones without any very serious complication. A tall, slender woman, fifty-four years of age fell, while the railway cars were in the act of running off the track, against the top of one of the seats, breaking eight of the ribs on the left side. The second, third, fourth, and fifth bones were fractured in front, about two inches and a half from their cartilages, while the eighth, ninth, tenth, and eleventh had given way behind, within a short distance of the spine. There was no displacement of any of the fragments, excepting the posterior one of the tenth rib, which projected slightly inwards towards the chest, and pierced the pleura. Excessive pain, dyspnœa, crepitation, and preternatural mobility marked the accident. The cough was violent, and recumbency impossible. The ordinary treatment was pursued, but without any material benefit, and the woman died exhausted at the end of the fourth day. The left side of the chest con-

tained about three ounces of coagulated blood, evidently furnished by the wounded pleura, but there was no sign of inflammation, except at the seat of the upper fracture, where the serous membrane was a little roughened by lymph and slightly ecchymosed. The lung was free from disease. All the other organs were sound.

Fracture of the ribs, without complication or displacement, is easily managed with the plaster or glass dressing, the surface being protected with a layer of wadding, or an ordinary flannel shirt. The bandage should be from two and a half to three inches in width, and drawn so tightly as to compel the patient to breathe chiefly with the diaphragm. A thin, flat compress, as a small, old towel, properly folded, to give greater support to the broken bone, may sometimes be advantageously used. In children I know of no better dressing for a fractured rib than one made of adhesive strips.

Similar dressings will answer in outward displacement of the fragments, only that a somewhat thicker compress may be necessary; if, on the contrary, the bone is driven inwards towards the chest, it is obvious that counterpressure applied to the extremities of the broken rib can be of no avail. When there is a wound, it might be easy enough to insinuate a small lever, to raise the bone, if not to its proper level, at least out of harm's way. My conviction, however, is that there should be no such interference, even when the depression is considerable, and the case most urgent, unless a fair trial has been made of other means, as the bandage and ordinary antiphlogistics, especially the lancet, leeches, and the free use of anodynes. If relief do not follow, and it is perfectly clear that the suffering depends upon the vicious projection of the ends of the fragments, no surgeon would hesitate to expose the parts, and use his best endeavors to rectify the displacement. Cases requiring such heroic measures must, however, be exceedingly rare, and hardly deserve formal mention in a work of this kind.

Wounds, contusions, and hemorrhage, consequent upon these accidents, must be treated upon general principles. When the blood proceeds from an intercostal artery, it may be necessary to enlarge the opening in the chest, or even to excise a portion of an adjacent rib, as in a case during our late war in the hands of Dr. Cuyler, of the army. If air collect within the chest in sufficient quantity to cause excessive respiratory embarrassment, it should be evacuated with the aspirator or a delicate trocar, introduced through a valvelike opening in the skin. Pain and cough are relieved in the usual manner. If the local distress is urgent, leeches may be used, followed by the application of a large opiate plaster.

Fig. 473.

Fractured Ribs united by Osseous Matter.

The patient observes the semierect posture, and remains within doors until he is able to exercise with impunity. If the bandage becomes insupportable, it must not be laid aside, but simply slackened.

Cases occasionally occur in which the rational symptoms of fracture of the ribs exist, but the characteristic signs are absent. The rule of practice, under such circumstances, is to treat the patient precisely as if the bones were actually broken.

The annexed drawing, fig. 473, from a specimen in my collection, affords an illustration of the manner in which the ribs, after fracture, are sometimes bound together by bony matter.

FRACTURES OF THE COSTAL CARTILAGES.

Fracture of the costal cartilages is so uncommon that a long time elapsed before surgeons were willing to believe in the possibility of such an occurrence. That it does take place, however, is a fact fully established by modern observation; and, what is remarkable, experience has shown that it is not always necessary for these bodies to be ossified before they can be broken, although this is usually the case. The accident, which is observed chiefly in elderly persons, is invariably produced by external violence, either directly or indirectly applied. The fracture is usually single, and the pieces which are most liable to suffer are the fifth, sixth, and seventh, owing probably to their great length and to their exposed situation. The direction of the fracture is commonly somewhat oblique, and the ends of the fragments often overlap each other, the posterior passing in

front or behind the anterior, which, from its connection with the sternum, serves as the fixed point.

The symptoms are similar to those of fractured ribs. The accident, whether simple or complicated, is, in general, comparatively free from danger. The broken ends are united by a clasp or ferule of bone, in which the cartilaginous tissue remains measurably unchanged. The reduction and maintenance of the fracture are often very difficult, but by a careful observance of the rules laid down under the head of fracture of the ribs, a cure may usually be effected in six or eight weeks. Malgaigne advises the use of a broad truss for keeping the fragments together, the pad making direct but gentle pressure upon their extremities. In obstinate cases they might be united with silver wire.

FRACTURES OF THE STERNUM.

This bone may give way in almost any portion of its extent, but more commonly near its middle, the direction of the fracture being generally somewhat oblique. Instances of longitudinal fracture of the sternum have been observed by Meyer, Malgaigne, and others, as the result of severe injury. Diastasis of this bone is exceedingly infrequent; and, so far as I know, there are only a very few well authenticated examples of fracture of the ensiform cartilage upon record. In one of these the patient, a man, twenty-eight years of age, met with the accident in a fall in which he struck the lower extremity of the sternum against the top of a candlestick, bending the cartilage at a right angle with this bone towards the spine, and causing by its pressure upon the stomach frequent and violent attacks of vomiting for a long time afterwards.

Blows, kicks, and falls are the ordinary causes of fracture of the sternum. Examples in which it was occasioned by violent muscular contraction during labor, have been recorded by different observers. In 1858 I attended, along with Dr. Rohrer, a case, in a large, heavy, muscular man, forty-seven years of age, who had received a transverse fracture of the upper part of this bone, from inordinate contraction of the sterno-cleido-mastoid muscles, in jumping, in a state of intoxication, off a shed eleven feet high. The heels, striking the ground obliquely, threw the body violently backwards, the head and neck coming in contact with the edge of a board. The fracture was, doubtless, occasioned by the effort which the man made to regain his equilibrium.

The ends of the fragments either preserve their natural relations, or, if displacement occur, it will be in the direction of the thoracic cavity, when the broken bones may lacerate some of the contained viscera, cause effusion of blood into the anterior mediastinum, and, perhaps, induce emphysema by wounding the lungs.

When the fracture is attended with displacement, it may usually be detected at a glance, or by merely passing the finger over the line of injury. Grating, sometimes audible at a considerable distance, and increased at every respiratory effort, is generally present. The pain is excruciating; recumbency is, for a time at least, impracticable; and there is great dyspnœa, along with cough, spitting of blood, and other evidence of internal injury.

In the case above referred to, there was, even several days after the accident, a marked depression at the site of the fracture, with considerable irregularity of the ends of the fragments, which was much increased when the patient sat up in bed. During recumbency, when he coughed hard, the hand, placed over the seat of the injury, could distinctly feel the fragments ride over each other, the upper evidently moving more freely than the lower. It seemed as if their edges had been bevelled off obliquely, that of the lower piece from above downwards and from before backwards, that of the upper in the opposite direction. Two or three times, as the man coughed, a distinct grating noise was heard. Percussion upon the spine, immediately opposite the fracture, had also the effect of displacing the ends of the fragments, and a similar result followed when firm pressure was made upon the anterior surface of the fragments. When the case was first seen, the upper piece was thrust backwards towards the thoracic cavity, fully one inch behind the level of the other; but it was easily restored to its natural situation by bending the chest backwards over a thick pillow. The pain at the seat of fracture was comparatively slight; but very distressing in the back of the neck and head. There was neither cough nor emphysema, and the fever that followed was slight.

The prognosis varies. When the thoracic organs have sustained much violence, the patient may die from shock, hemorrhage, or emphysema; or, surviving the immediate effects of the accident, he may perish from the consequences of inflammation of the

lungs, abscess of the mediastinum, or disease of the bone itself. In the Mütter Museum there is a skeleton in which a fracture of the sternum, near its middle, had undergone perfect repair, although not without marked deformity from the want of accurate apposition. Evidence of fracture exists in several other bones, and there must also have been a remarkable predisposition to the development of exostoses, the number of which is very considerable.

The *treatment* is, in great measure, restricted to the application of compresses and an immovable bandage, to afford support to the chest and quietude to the intercostal muscles. In the event of serious internal complication, local and general bleeding, active purgatives, antimonials, and anodynes may be required, along, perhaps, with medicated fomentations. If the fracture be simple, no attempt should be made to rectify the depression of the offending fragment, unless it is causing compression of the heart or lung. In such a case, and also when there are loose pieces of bone projecting into the chest, restoration should promptly be effected at all hazard. To accomplish this, the patient may lie across a table, over a double inclined plane, in order to extend the spine, and afford the muscles attached to the extremities of the sternum an opportunity of drawing the ends of the broken bone asunder. While this is being done, pressure should be made upon the parts in a direction opposite to that of the displacement, at the same time that the lungs are, if possible, thoroughly distended with air. Or, this failing, the bone, the body being still in this position, may, perhaps, be raised with a small, delicate elevator, used subcutaneously, supposing that a wound does not already exist. If this also prove unsuccessful, the urgency of the case will fully justify the application of the trephine, or the removal of a sufficiency of bone with a Hey's saw. A similar procedure may be necessary when an abscess forms in the anterior mediastinum, or when a portion of the sternum is ulcerated or necrosed, although in the former event it may not always be possible to reach the fluid.

In fracture of the ensiform cartilage with outward protrusion of the fragment, the chief reliance must be upon systematic and long-continued compression with a well-adjusted pad, confined with a suitable bandage. When the point of the bone is driven backwards towards the spine, forming a right angle with the lower extremity of the sternum, and causing more or less suffering by its pressure upon the stomach, as nausea and vomiting, the only resource is excision, an operation requiring some care and skill for its successful execution, but in every respect proper.

FRACTURES OF THE VERTEBRÆ.

The vertebræ are so compactly constructed, so strongly articulated, and so thickly covered by muscles, as to render their fracture a matter of great difficulty. The most common causes are violent blows or falls, giving rise at the same time to severe injury of the soft parts. Occasionally the lesion is produced by contre-coup, as when a person falls from a great height and alights upon his feet, the force being transmitted along the extremities and the pelvis to the spinal column, where, concentrating upon a particular bone, it breaks its substance or severs its ligamentous connections. Any part of such a bone may give way, its body, plates, and processes being all liable to yield under the influence of the causes here mentioned. The symptoms and effects of this lesion must be considered with reference to the different divisions of the vertebral column, as the cervical, dorsal, and lumbar, each possessing certain peculiarities growing out of its relations with the spinal cord and the nerves which are detached from it.

In fracture of the *cervical vertebræ*, the symptoms vary according to the situation of the affected bone. Thus, if the lesion is above the fourth piece, or the principal origin of the phrenic nerve, and the spinal cord is at all compressed, the diaphragm will be paralyzed, the respiration will be more or less embarrassed, and death will follow, either immediately, or within a short time after the accident. If, on the other hand, the fracture is seated below this point, there will be paralysis, to a greater or less extent, of all the extremities, embarrassment of breathing, relaxation of the anal sphincters, incontinence of urine, and tympanitic distension of the abdomen. When the fracture is oblique, one arm is sometimes more disabled than the other. Recovery may ensue if the injury of the soft parts is not very severe, but in most cases death occurs in from three to five days.

Fracture of the *odontoid process* is very uncommon, and generally proves promptly fatal from injury to the spinal cord. Now and then, however, a remarkable exception is found. Thus, in a case related by Dr. Willard Parker, the patient survived the accident five months, when he suddenly expired from displacement of the process, during some inad-

vertent movement of the head, a result favored by the destruction of the occipito-axoid ligament. The dissection showed that the odontoid process had been completely broken off, and that its lower extremity had been turned backwards towards the spinal cord, as exhibited in fig. 474. The patient, a man, forty years of age, had been thrown violently from his carriage, alighting, about fifteen feet off, upon his head and face. After recovering from the immediate effects of the accident, he was able to resume his business as a milkman, which he followed, diligently and uninterruptedly, every day for four months. He complained, however, constantly of pain in the occipito-cervical region, and was always obliged to support his head, which he was incapable of rotating. The only visible deformity was a protuberance of the neck, just below the base of the occiput, to the left of the median line, with a corresponding indentation.

Fig. 474.

Fracture of the Odontoid Process of the Axis: *a*, Broken Surface; *b*, Odontoid Process.

Hyrtl has reported a case of fracture of the odontoid process which occurred very unexpectedly in a woman while sitting up in bed to take her meal. Death was instantaneous. The bone was found to be diseased. In a case related by Professor Flint, the bone, inflamed and softened, gave way in consequence of a blow inflicted upon the neck a few months before.

In fracture of the *dorsal vertebræ*, the upper extremities are free from paralysis, unless the injury is seated very high up, when they may participate in this affection with the subdiaphragmatic portions of the body. The bowels, in either case, will be torpid and distended with gas, and the bladder unable to expel its contents. Life is seldom prolonged beyond a fortnight, although in some rare cases it lasts for several months. In this event, the bowels and bladder may partially regain their original tone, but the urine soon becomes loaded with phosphates, and the lining membrane of the bladder suffers from subacute inflammation, adding thus greatly to the patient's discomfort.

When the *lumbar vertebræ* are broken, the lower extremities are generally deprived both of volition and sensibility, the feces pass off involuntarily, and the bladder is unable to relieve itself. Life usually lasts longer than in fracture of the dorsal vertebræ, the paralysis not extending so high up, and, consequently, not involving so many important organs. In the majority of cases, the patient dies in five or six weeks; but he may survive a much longer time, the bladder suffering as in fracture of the other divisions of the spine.

Priapism is an occasional symptom of these accidents; it is evidently dependent upon lesion of the spinal cord, and is most liable to occur when the injury is situated high up in the neck. It is generally associated with paralysis, and is nearly always an early phenomenon, manifesting itself within the first forty-eight hours, and often continuing, more or less obstinately, up to the moment of dissolution. It is sometimes present even when there is complete deprivation of sensibility and consciousness.

The sexual powers are sometimes remarkably preserved after these injuries, as in an interesting case recorded by the late Professor Childs, of New York. The man, who lived for fifty-three years in a perfectly paraplegic condition, consequent upon a fracture of the twelfth dorsal vertebra, was married at the age of thirty-six, and became the father of six children. The spinal cord was completely atrophied below the seat of the injury. The capacity for coition was unimpaired, but there never was any venereal orgasm. Sensation existed only in front of the abdomen, of the scrotum, and of the thighs. The urine was expelled, after the first four weeks, by a painful effort of the will, aided by a loop of rope tightly twisted with a stick over the hypogastric region.

The symptoms here enumerated may follow fracture of any portion of a vertebra, except, perhaps, that of the spinous process, when the suffering is generally comparatively slight, unless the lesion is complicated with serious mischief of the spinal cord.

The concussion of the spinal marrow, which so frequently attends these accidents, especially when induced by severe falls, or blows, may be so violent as to cause death almost instantaneously. When the case is less urgent, the patient may live, but will be likely to suffer, temporarily, from loss of power, partial or complete, of the sphincter muscles of the bladder and anus, and, permanently, from paralysis of the lower extremities, if not also of the upper.

Fracture of the *spinous* processes of the vertebræ occasionally occurs independently of the bodies of these pieces, as seen in fig. 475, the usual exciting cause being a blow, fall,

or kick. Preternatural mobility and lateral displacement, with more or less contusion and discoloration of the soft parts, are the most reliable phenomena.

Fracture of the *arches* of these bones, of which the accompanying cut, fig. 476, affords a good illustration, is often comminuted, and attended with depression of the fragments, some of which may be driven into the substance of the spinal cord, crushing and pulpifying it. It is generally produced by violence directly applied, and is frequently quite as dangerous as a fracture of the bodies of the vertebræ.

Fig. 475.   Fig. 476.
Fracture of the Spinous Process.   Fracture of the Vertebral Arches.

The *transverse* processes of the vertebræ can only be broken by excessive force, as the passage of a ball, or a severe blow, or a fall from a considerable height. Hence the result of such accidents is commonly very unfavorable.

The *diagnosis* of fracture of the spine is usually a matter of inference rather than of positive conviction. Its most important elements are the mode of production of the injury, and the paralysis of the extremities, but it should be recollected that this symptom may depend entirely upon lesion of the spinal cord, unconnected with fracture of the vertebræ; and cases have been observed by Cooper, Dupuytren, South, and others, in which the effects of violent strains of the spinal ligaments and muscles closely simulated fracture of these bones. Owing to the small size of these bones, and the manner in which they are covered in by the muscles of the back, it is generally impossible to detect either crepitation, deformity, or preternatural mobility. All these phenomena may, however, be present in fracture of the spinous processes.

Dissection, after an injury of this kind, usually reveals more or less displacement of the broken bone, which is sometimes quite comminuted, laceration of the connecting ligaments, and injury of the spinal cord, with more or less extravasation of blood in the spinal canal and the surrounding parts. The cord is compressed, bruised, pulpified, perhaps nearly completely severed, pieces of bone sometimes being imbedded in its substance, as shown in fig. 477.

Fig. 477.

The *prognosis* of these accidents may be inferred from what has been said respecting their symptoms and effects. If the patient escape immediate destruction, he will almost certainly succumb under his suffering at no very remote period; or, if life be spared, be doomed to carry on a miserable, bedridden existence, palsied and otherwise crippled in the exercise of some of his more important functions. A remarkable case of fracture of the fifth dorsal vertebra, with displacement of the bodies of the third and fourth of these bones, in which, notwithstanding the complete division of the spinal cord, life was prolonged for two months, has been recorded by Dr. Parkman, of Boston.

Fracture of the Vertebræ.

In the *treatment* of fractured vertebræ, very little is to be done in the way of restoring displaced fragments, all such attempts being not only uncertain, but, even if successful, likely to aggravate the danger by the additional mischief that is inflicted upon the spinal cord. The same remark is applicable to the operation of cutting down upon the injured part, and

removing the offending portion of bone with the trephine or saw, as originally suggested by Paul of Ægineta, and first practised, in 1814, by Mr. Henry Cline, of London. Of 38 cases, tabulated by Dr. John Ashhurst, in which this procedure has been employed, including those of Barton, Rogers, Potter, Blackman, Hutchinson, and Stephen Smith, 29 died, 3 were relieved, 2 were not benefited, and the result is unknown in 4. In the cases reported as relieved, the improvement was only partial, a circumstance that might have been expected when it is recollected how seriously the spinal cord is generally injured by the depressed fragments. The operation, although difficult, on account of the great depth at which the broken bone is situated, may be executed with but little loss of blood; and I must confess that, notwithstanding the want of success which has hitherto attended it, I should feel strongly tempted to resort to it, if the symptoms were such as to render it certain that the lesion was accompanied by depression.

Whether an operation is performed or not, it is clearly the duty of the surgeon to adopt prompt measures for the prevention of inflammation. With this view, blood is freely taken from the arm, and also by leeches from the seat of the injury; the bowels are relieved by purgatives or stimulating enemas, and pain is alleviated by full doses of anodynes, combined, if there be much fever, with depressants. The bladder is carefully watched, and the urine, if retained, is drawn off regularly twice or thrice a day, instead of allowing the catheter to remain permanently in the bladder. The patient is kept on his back, upon an air- or water-bed, his head resting upon a low pillow, and his position being as seldom changed as possible. Great care is taken not to turn him upon his face, as he might be almost instantly asphyxiated while in this situation, from the imperfect descent of the diaphragm, caused by the pressure of the abdominal viscera, on account of the paralyzed condition of the abdominal muscles, and their consequent inability to offer any resistance to the weight of the body. After the lapse of a few weeks, the back and limbs should be frequently rubbed with stimulating liniments, and a large issue established in the vicinity of the injury with the actual cautery. Along with these means, trial may be made of small doses of strychnia, in union with iron, quinine, and mercury, especially if there is evidence of the existence of spinal meningitis, or of extravasated blood. All treatment of this kind will, of course, be useless when the spinal cord has been crushed.

When the lesion is confined to the spinous processes, the fragments must be moulded into shape, and retained by two long, thick compresses, stretched along the side of the spine, and secured with a circular bandage, fastened by a scapulary. If the broken pieces, however, are much shattered, so as to preclude the possibility of reunion, they should be removed.

FRACTURES OF THE PELVIC BONES.

α. The *innominate bone* may give way in various parts of its extent, but the one which is most apt to suffer is the upper crest, owing probably to its exposed situation.

The *acetabulum* is sometimes broken by a severe blow upon the hip, or by a counter-stroke, as when a person falls upon his knee or foot, thereby driving the head of the femur into the pelvis. The most common form of the accident is that in which the lip or border of this cavity is chipped off, either as a single piece of variable size and shape, or where it is broken into several fragments. In the adjoining cut, fig. 478, from a preparation in the possession of Professor Neill, the fracture runs in a semicircular direction through the acetabulum. Occasionally the floor of the acetabulum is driven by the head of the thigh-bone into the pelvic cavity, so as to inflict more or less injury upon its contents. In young sub-

Fig. 478.
Fracture of the Acetabulum.

jects, the innominate bone has been found separated at the acetabulum into its three primitive pieces. In a case of this kind, dissected by Moore, the head of the femur had completely penetrated the pelvic cavity, the limb, placed in a state of slight flexion and adduction, being shortened two inches.

Whatever may be the site, form, or extent of these fractures, they can happen only through the agency of direct mechanical violence, which, at the same time, generally seriously compromises the soft structures, both outside and inside the pelvis. The most frightful accidents of this kind that have fallen under my observation have been the result of railway injury, caused by the body being jammed in between a car and a wall, literally crushing the bone, and fatally implicating the bladder and other organs.

The symptoms will necessarily vary according to the seat and extent of the fracture. When the bone has given way at the cotyloid cavity, the nature of the case may usually be recognized by the circumstance that the head of the femur is drawn upwards, and the great trochanter somewhat forwards, so that the limb is diminished in length, and the foot inverted. When the head of the thigh-bone is impacted in its new position, the limb may be firmly fixed, as in dislocation, but, in general, it will be found to be more or less movable, and to afford distinct crepitation when an attempt is made to rotate it. Fracture of the brim of the acetabulum is generally associated with dislocation of the femur, and hence, although the reduction of both injuries may be sufficiently easy, yet the displacement is sure to recur the moment the efforts required to effect this object cease.

The diagnosis of these accidents is very uncertain, and, in many cases, their true nature is only discovered on dissection. The most reliable signs are, shortening from six lines to an inch and a half, inversion of the foot, unnatural elevation of the great trochanter, excessive pain on pressure over the joint, crepitation, generally more decided than in fracture of the neck of the femur, and prompt effacement of the deformity under extension and counterextension, followed by an immediate return of it when these efforts are discontinued.

The prognosis of fracture of the acetabulum is variable. In many cases, the injury inflicted upon the bones and soft parts is so great as to cause death either from shock or from inflammation. When the patient recovers, he is usually maimed for life, as the case is either misunderstood, or, if understood, unsuccessfully treated, often as a necessary consequence of the peculiar character of the injury, and, therefore, without any just blame as it respects the skill of the professional attendant. In the female, a fracture of the floor of the acetabulum, accompanied with great displacement, might seriously interfere with parturition, and in both sexes the pressure of the bone upon the pelvic nerves might become a cause of severe and protracted neuralgia.

In regard to the treatment of these injuries it is difficult to lay down any definite plan. When the floor of the cavity is broken, reposition is, of course, impracticable, and the less, therefore, the case is interfered with the better. When the fracture involves the rim of the bone, and coexists with displacement of the femur, an attempt should be made to maintain the parts in their proper relations by keeping the limb in a straight line with a long side splint and a weight appended to the foot, while the joint is carefully supported with a broad compress confined by a suitable band passed around the pelvis.

In fracture of the *pubic* and *ischiatic* bones, the corresponding limb is either somewhat shortened, or it retains its natural length; the fragments are pushed either directly downwards, forwards towards the femur, or backwards towards the acetabulum; the patient is unable to sit, stand, or walk; and on placing one hand upon the ilium, and the other upon the pubes, crepitation may usually be perceived. A well-characterized fracture of the pubic and ischiatic bones is delineated in fig. 479, from a preparation in the collection of Professor Neill. A very interesting case, of a similar nature, attended with fatal injury of the bladder, occurred a few years ago under the observation of Dr. John W. Lodge, and is fully described in the American Journal of the Medical Sciences for October,

Fig. 479.

Fracture of the Pubic and Ischiatic Bones.

1865. A case of fracture of the body of the pubic bone by muscular contraction, in a very stout, hard-working woman, forty-three years of age, in the act of lifting a heavy stone, has been reported by Letenneur, of Nantes.

The pubic bones are sometimes severed at their symphysis. Of four cases collected by Malgaigne, the accident, in three, was occasioned by muscular contraction during the forcible abduction of the thighs, and of these two perished. The same author has analyzed seventeen cases in which the separation occurred during parturition, with a loss of ten. Maret met with an instance of fracture of the pelvis in which he was obliged to excise nearly
the whole of the body of the pubic bone by an incision through the labium. The fragment had been pushed forward and inward, and interfered with the introduction of the catheter, rendered necessary on account of retention of urine. The patient, a girl eighteen years of age, not only made a good recovery, but afterwards gave birth to two children in easy and natural labors.

Fracture of these bones is generally produced by severe injury, and is, therefore, nearly always complicated with serious lesion of the soft parts. Cappelletti met with an instance in which their branches were broken by violent muscular contraction, as the patient, a man, fifty-four years old, was jumping out of his carriage, while the horses were running away. A case of fracture of the anterior superior spinous process of the ilium by muscular contraction has been reported by Dr. Joy and Dr. McWhinnie, of Canada.

Fracture of the crest of the *ilium* is characterized by more or less displacement, preternatural mobility, and crepitation; the pain is severe, and progression impracticable. The nature of the accident is sometimes rendered apparent by the existing deformity and by slight manipulation.

Besides the above symptoms, denotive of fracture of different parts of the innominate bone, there are always more or less contusion of the external soft parts, and not unfrequently, also, serious injury of the pelvic viscera, followed by loss of motion of the inferior extremities, retention of urine, and other distressing affections. The prognosis should, therefore, be very guarded, as such accidents are generally fraught with danger, death often occurring in a few days from inflammation or extravasation of urine, or, at a later period, from abscess, phlebitis, and other mischief. Of 65 cases of fracture of the pelvic bones, analyzed by Dr. J. W. Lyon, 41 recovered, and 24 died, one-half of the latter having labored under rupture of the bladder.

Owing to their peculiar character, it is usually found very difficult to reduce these fractures, or to prevent relapse after this has been done. To effect restoration, our main reliance must be upon pressure, while the maintenance is best accomplished by well-arranged compresses, secured by a belt or an immovable bandage. Even when no displacement exists, great comfort will be experienced from such support. In any event, the utmost quietude must be enjoined; the patient must lie upon his back, his shoulders being elevated, and the thighs flexed, to relax the muscles about the pelvis; inflammatory action is promptly dealt with, and the bowels are moved as seldom as possible. The bladder is carefully watched, retention of urine being relieved with the catheter. An air-bed sometimes affords great comfort in such a condition.

β. The *sacrum* may be broken by falls, blows, gunshot violence, and similar injury, usually in a transverse or oblique direction; a comminuted condition is sometimes observed, and Richerand met with a case in which the fracture was vertical. The lesion is generally discoverable, especially when attended with displacement, by mere manual examination, as the patient lies upon his abdomen. It is accompanied with severe pain at the affected part, and great difficulty in walking, associated, when there is involvement of the sacral nerves, with paralysis of the lower extremities, retention of urine, and involuntary discharge of the feces. The danger attending this accident is always considerable, on account of the mischief done to the soft parts; hence, even if the patient survive the immediate shock of the injury, he may perish afterwards from the effects of inflammation of the pelvic viscera.

When the fragments are pushed inwards, reposition may be attempted by the insertion into the rectum of a stout bougie, a lithotomy scoop, or a vesical sound, care being taken not to do any injury to the mucous membrane; or, if the displacement is very slight, the bone may be left in its new situation, as it can then not do any harm. Backward displacement may easily be remedied by pressure with the finger, relapse being prevented by a compress and a T bandage. Recovery is promoted by rigid recumbency, antiphlogistics, and the use of a water bed.

A remarkable case of compound fracture of the sacrum, caused by a railway accident, attended by discharge of urine through the wound, and ultimately followed by recovery, has been reported by Dr. H. D. Burlingham, of Illinois, in the American Journal of the Medical Sciences for April, 1868. The bladder was supposed to have been torn at its neck. The urine, after the first few days, was allowed to flow off constantly through the catheter.

γ. The *coccyx* is sometimes broken by a fall, by a kick upon the buttock, or by the passage of the child's head in labor. The accident is most common in elderly subjects, in whom the joints of this bone have been destroyed by a deposit of osseous matter. The characteristic signs are, preternatural mobility, acute pain, and crepitation on introducing

the finger into the bowel.   Paralysis of the bladder and rectum is a frequent, if not general, phenomenon.   During labor, the occurrence of the injury is sometimes rendered evident by a sense of yielding and a peculiar noise perceived by the attendant as he is engaged in supporting the perineum.   If displacement exist, it is remedied by pressure upon the surface and counterpressure with the finger in the rectum.   It is very important, especially in the female, that the coccyx should be preserved in a continuous line with the sacrum, otherwise serious deformity of the pelvis may ensue, interfering with defecation and parturition.   After the reduction has been effected, the parts should be supported with a compress, confined by adhesive strips; perfect quietude and lateral recumbency should be observed; and the bowels, without being acted upon at all frequently, should be maintained in a strictly soluble condition.   Paraplegia and violent neuralgia occasionally follow this accident, owing to injury sustained by the nervous plexus of the pelvis.

2. SUPERIOR EXTREMITY.

FRACTURES OF THE BONES OF THE HAND AND FINGERS.

The symptoms of fracture of the bones of the thumb and fingers are so obvious as to render any formal account of them unnecessary.   The treatment is by a pasteboard, leather, felt, plaster, or rubber splint, accurately moulded to the shape of the member and the palm of the hand, to which it must be well secured by appropriate rollers.

The *metacarpal* bones are sometimes broken by machinery, and I have met with a number of instances in which the fourth and fifth of these pieces had given way under a blow of the fist, the part struck being, in one of the cases, the face, and another the forehead.   Such accidents are characterized by marked displacement upon the back of the hand, from the projection of the anterior fragment, with distinct crepitation and swelling of the soft parts, but hardly any pain.   In young subjects these bones occasionally give way at their epiphyses.   The treatment consists in the use of a well-padded tin case for the palm of the hand, extending from just above the wrist to the ends of the fingers, and of a short, narrow splint for its dorsal surface, firm pressure being made with it over the seat of fracture.   Union generally occurs in a month, with little if any deformity.

Occasionally the fifth bone alone is broken, as I have witnessed in at least half a dozen cases.   The prominent symptom in all was a marked posterior projection.   Great circumspection is necessary in the treatment of this fracture, otherwise deformity will be sure to follow.

The *carpal* bones are never broken, except by direct violence, which always seriously implicates the soft parts, not unfrequently necessitating the removal of a portion, if not of the entire hand.   The nature of the accident is usually apparent from the attendant deformity, the excessive pain, loss of function, and crepitation on manipulation.   Reposition of the fragments having been effected by pressure and counterpressure, retention is secured by means of two splints, ether of binder's board or wood, long enough to extend from the middle of the forearm to the ends of the fingers, the hollow of the hand being well padded, and the limb supported in a sling.

There are no fractures in any region of the body where the surgeon will find a finer field for the exercise of his skill in saving mutilated structures than in those of the hand, thumb, and fingers.   It is here, emphatically, that conservative surgery may often display its highest excellence.   Bad as many of the cases are, there are very few in which, if a proper attempt be made, the parts may not be treated on general principles with a fair prospect of success.   Occasionally a joint may be lost, and still a thumb or finger be of great use to the patient.   It is only in the most desperate cases that primary amputation should be resorted to; in all others an attempt should be made to save the parts.

FRACTURES OF THE SHAFTS OF THE RADIUS AND ULNA.

The radius and ulna may be broken conjointly by direct violence, or, as more frequently happens, by a counterstroke, as when a person falls upon the hand, and the force is concentrated by transmission upon the forearm.   The fracture, although it may occur at any point, is most common in the inferior half of these bones, and rarely takes place at the same level, whatever may be its cause.   In general, too, it is oblique, and not transverse, as is usually supposed.   The nature of the accident is commonly sufficiently apparent

from the angularity of the fragments, as seen in fig. 480, and their preternatural mobility, to say nothing of the facility of eliciting crepitation on rotating the hand. The patient experiences an inability to supinate and pronate the limb, the forearm is in a state of semiflexion, and acute pain is felt at the seat of the injury.

The chief danger in this fracture, as it usually exhibits itself, is from the tendency of the ends of the fragments to sink inwards into the interosseous space, and to become united by a common callus, thereby materially impeding the usefulness of the limb, by destroying the functions of supination and pronation. With ordinary care, however, such an accident is not likely to happen, and, in most cases, the consolidation is completed in from thirty to thirty-five days, without any deformity or ultimate inconvenience. The vicious union here mentioned is well show in fig. 481, from a preparation in my collection.

The fracture having been adjusted in the ordinary manner, the forearm is bent at a right angle with the elbow, and enveloped by a roller extending from the fingers upwards.

Fig. 480.　　　Fig. 481.

Malapproximation of the ends of the Fragments in Fracture of the Ulna and Radius.

Fracture of the Shaft of the Radius, with vicious Union.

Two thick binder's board splints are next applied along the anterior and posterior surfaces of the broken bones, and secured with the remainder of the bandage. They should be a little wider than the limb, and long enough to reach just from below the elbow to the extremities of the fingers, both being well covered with wadding, and accurately moulded to the parts. The hand and forearm are then suspended in a broad sling, with the thumb looking directly upwards.

I have myself for many years entirely dispensed with the compresses upon which so much stress has generally been laid for counteracting the tendency of the ends of the fragments to approach each other at the interosseous space. I am satisfied that all the pressure that can be required, at least in ordinary cases, may be effected by the two splints which are usually employed in the treatment of fracture in this situation. The bandage, too, has received a great deal of unjust blame in these cases, it being alleged that, if applied directly to the surface, it will force the bones together, and thus lead to vicious union. It would unquestionably be easy enough to produce such an effect, but this would be an abuse, and not a proper use, of the bandage, its appropriate office being to afford equable support to the muscles of the broken limb, and to prevent swelling and spasmodic action. Whenever it causes such an amount of compression as to force the fragments towards each other, it cannot fail to excite pain and inflammation, if not worse consequences. It is the manner, then, in which the application is made, and not the application itself, that is objectionable in the treatment of this fracture. As to the splints, they should be carefully moulded to the shape of the limb, a narrow interval being left between them at its radial and ulnar borders. When binder's board splints cannot be obtained, light pieces of wood may be used.

When the fracture is multiple, consisting, for example, of three fragments, the intermediate one, having lost its support, may have a tendency to sink in towards the interosseous space. To counteract this disposition, a thick, narrow pad may be placed along the border of the loose piece, in an opening in the anterior splint, so as to enable the surgeon to make the pressure more firm and direct. But even here such an expedient will rarely be necessary, if the parts have been moulded into their proper position prior to the application of the apparatus.

FRACTURES OF THE ULNA.

Fractures of the ulna may with great propriety be divided into those which take place in its body, its inferior extremity and its two principal processes, the olecranon and coronoid.

1. *Shaft.*—The body of the bone is most commonly broken in the lower half of its

extent, in an oblique direction, as exhibited in fig. 482, from causes acting directly upon the forearm. The accident may, however, be produced by a counterstroke; and at least one instance is known where it was occasioned by muscular action in wringing clothes, the patient being a stout, healthy girl of eighteen. The fracture is evinced by a marked depression at the inner border of the forearm, by the mobility of the fragments, and by the crepitation on rotating the hand. The lower fragment alone is generally displaced, being drawn over towards the interosseous space by the inferior pronator muscle, while the other, from its firm connection with the humerus, remains stationary. An exception to this rule is seen in the adjoining figure.

Fig. 482.
Great care is necessary in the treatment of this fracture, lest the upper end of the lower fragment retains the vicious position into which it is forced at the time of the accident, and so is ultimately soldered to the inner margin of the radius. To prevent this occurrence, the hand should be permanently inclined towards the thumb, by two splints, the extremities of which are rendered somewhat sloping from behind forwards, in a direction opposite to that of the splints sometimes employed in the management of fracture of the corresponding end of the radius. Such an expedient will be much more efficient than the long, thick, narrow compress, generally recommended for that purpose.

The head of the ulna is sometimes broken off, either separately, or along with the head of the radius. The circumstance is easily detected by the mobility of the part, by the disabled condition of the wrist-joint, by the severity of the pain, and by the concomitant distortion. The treatment is conducted with two splints, aided, if necessary, by two compresses applied directly over the seat of the fracture.

2. *Olecranon Process.*—Fracture of the olecranon, fig. 483, is caused either by direct violence, or by the inordinate action of the three-headed extensor muscle, attached to its upper extremity. Of 35 cases collected by Malgaigne, 27 were the result of falls, 3 of blows, and 5 of muscular contraction. Situated at various points of its extent, the fracture may be transverse or oblique, single or multiple, simple or complicated.

Fracture of the Shaft of the Ulna.

Fig. 483.

Fracture of the Olecranon Process.

The symptoms are semiflexion of the limb, impossibility of extending the forearm, a hollow at the back of the elbow, as seen in fig. 484, and a movable prominence at the postero-inferior surface of the arm, along with more or less pain and swelling. The interval between the two fragments varies from one and a half to two inches, and may be augmented or diminished at will by moving the forearm. The radius may be rotated upon the ulna, and crepitation may be elicited by the approximation of the extremities of the broken bone. When the tip of the olecranon is severed, there is no separation of the fragments; and the same thing may happen when the fracture, whether oblique or transverse, is situated above the ligamentous expansion of the extensor muscle.

Fig. 484.

Fracture of the Olecranon Process.

The union of this fracture is generally fibro-ligamentous, as in fig. 485, from a specimen in my collection. The causes of this occurrence are, want of proper nourishment of the upper fragment, difficulty of maintaining apposition, and inordinate deposit of synovial fluid, all, but especially the first, interfering with the healing process. I have, in a few instances, seen osseous union; but this is extremely rare, and is not at all likely to happen if there be any considerable separation of the fragments, or if the fracture extend through the lower part of the process. The period required for the repair of the injury varies

from six to eight weeks; but many months elapse before the patient regains a good use of his limb. When the lesion is of a complicated nature, violent inflammation of the elbow-joint may arise, ending in permanent ankylosis, or in caries and necrosis of the bones.

Fig. 485.
Fracture of the Olecranon Process United by Fibrous Tissue.

The treatment consists in maintaining the limb in an extended position, by means of a wooden splint, long enough to reach from a level with the wrist-joint to within four inches of the shoulder, as represented in fig. 486, from Hamilton. A roller having been

Fig. 486.
Hamilton's Apparatus for Fracture of the Olecranon Process.

applied from the fingers upward, the small fragment is drawn into its proper place, where it is confined by a few long adhesive strips and a compress, the whole being firmly secured by carrying the roller around the joint somewhat in the form of the figure 8; or, instead of this, the arm is bandaged from the shoulder downwards, so as to obtain a more perfect control over the extensor muscle, the great agent in effecting displacement. Passive motion is instituted at the end of four weeks, and frequently renewed, to prevent ankylosis. When the fracture is associated with severe injury of the soft parts, leeches, fomentations, and other antiphlogistic measures must be employed.

Some practitioners give a decided preference to the flexed position in the treatment of this fracture, and there is no doubt that such a position vastly enhances the comfort of the patient, as it enables him to take out-door exercise and attend to business. The cure, however, is less perfect and at the same time more protracted, owing to the greater difficulty of keeping the ends of the fragments in accurate apposition. Dr. E. A. Clark, of St. Louis, has devised a special apparatus for the purpose, consisting of a band of ordinary sole-leather buckled around the lower part of the arm, and attached by means of two leather straps at the anterior and posterior surfaces of the forearm to a stout buckskin glove. The forearm is well bandaged and supported at an angle of forty-five degrees. A similar contrivance, in which the counterextension is made from the side of the chest by means of adhesive strips, and the apparatus elongated by a ratchet connected with two steel bars, has been invented by Dr. Henry A. Martin, of Boston.

3. *Coronoid Process.*—A considerable number of cases of fracture of the coronoid process of the ulna, fig. 487, have been reported, both in systematic treatises and in

Fig. 487.

Fracture of the Coronoid Process.

medical periodicals, but it is very questionable whether even a minority of them should be considered as true examples of that lesion. I have myself never met with the accident; Professor Hamilton, who has investigated the subject with great care, is very decidedly

of opinion that most of the published cases are unworthy of acceptance, either because they were badly observed or imperfectly reported, and because the existence of very few of them have been verified by dissection. Recently the whole subject has been reëxamined by Dr. R. M. Hodges, of Boston, who has cited a number of examples clearly establishing the occasional occurrence of this fracture. In the case of a boy, nine years of age, treated by Dr. A. A. Scott, of Missouri, to whom I am indebted for the particulars, the coronoid process formed a distinct prominence upon the anterior and inferior surface of the humerus, a short distance above the joint, movable from side to side, the olecranon being at the same time displaced slightly backwards, and the forearm somewhat flexed. The accident was caused by a fall upon the hand while the arm was forcibly extended.

It has generally been supposed that the accident may be caused by inordinate contraction of the anterior brachial muscle; but as this muscle is not attached to the coronoid process, it is impossible for it to produce such an effect. The most reasonable conclusion, therefore, is that fracture of this prominence is always the result either of direct injury, as a fall, a blow, or the passage of the wheel of a carriage, or of force applied to the hand, pushing the ulna and radius violently upwards against the lower extremity of the humerus while the forearm is in a state of extreme extension and the body is impelled in the opposite direction. The accident is usually complicated with fracture, or fracture and dislocation of the elbow-joint.

In whatever manner the fracture is produced, the diagnosis is always attended with unusual difficulty. The ulna, having lost its support in front, will necessarily be drawn backwards and upwards by the action of the three-headed extensor muscle, so that the injury will present all the features of a dislocation of the bone in this direction, the prominence of the olecranon being characteristic. The patient is unable to flex the limb, and the detached portion of bone may be felt immediately above the elbow, where it may readily be grasped and moved about, especially soon after the accident, before any swelling has set in. By bending the forearm at a right angle with the arm, and drawing down the fragment of bone, crepitation might possibly be elicited, but this must, in any event, be very faint and indistinct. The accidents with which the injury is most liable to be confounded are fracture of the humerus and dislocation of the ulna and radius backwards.

The union must always necessarily be fibro-ligamentous, as is sufficiently evident when we reflect upon the small size of the detached fragment, the difficulty of keeping it in place, its imperfect nourishment, and its connection with the joint; circumstances which are so many impediments to the formation of osseous matter. In young subjects, and under proper management, a cure may generally be looked for in four or five weeks.

Apparatus for Fracture of the Coronoid Process.

The *treatment* is conducted with a view to the thorough relaxation of the flexor muscles of the limb. For this purpose, the forearm, after having been properly bandaged from the fingers up as far as the elbow, and the arm from the shoulder downwards, in the opposite direction, is placed at a right angle, as in fig. 488, in a tin case or suitable splints, and supported by a sling, care being taken to prevent the radius and ulna from slipping backwards, away from the condyles of the humerus. The fulfilment of this indication will generally be materially aided by the use of adhesive straps, carried around the joint in the same manner as in fracture of the olecranon. Whatever apparatus be employed, it should be long enough to insure complete immobility of the hand, the fingers being left free. Passive motion should be instituted at the end of four weeks, and perseveringly renewed from time to time, lest ankylosis ensue.

An *epiphyseal* fracture of the extremities of the ulna is an occasional occurrence: for the heads of this bone are not united to the shaft by osseous matter until after the eighteenth year, and often not so soon. The exciting cause is external violence: the symptoms are such as characterize ordinary fracture, except that there is less distinct crepitation, and the treatment, in the upper fracture, is similar to that of fracture of the olecranon, while in the lower two straight splints are required.

FRACTURES OF THE RADIUS.

1. *Shaft.*—Fracture of the body of the radius may take place independently of that of the ulna, as shown in fig. 489, and is the more frequent accident of the two : its most common seat is the inferior half of the bone ; its ordinary cause, a fall upon the palm of the hand. Dr. Packard has reported a case of fracture of the upper portion of the radius from violent muscular exertion in driving a pair of horses.

Fig. 489.

Fracture of the Shaft of the Radius.

The symptoms are usually well marked, there being more or less deformity, preternatural mobility, inability to perform the motions of pronation and supination, and crepitation upon rotating the hand. The ends of the fragments have a singular tendency to approach the interosseous space, and hence, if the case be not judiciously managed, there is apt to be permanent distortion, with partial loss of function of the limb. One of the evil consequences of this tendency is the want of osseous union, or the formation of a false joint within two and a half or three inches of the wrist. A number of well-marked examples of this kind have fallen under my observation, and I know of no fracture where an unskilful surgeon may show his ignorance to greater disadvantage.

The limb, being bandaged in the usual manner, is steadied by two splints extending as far forwards as the extremities of the fingers, the hand being inclined inwards towards the ulna, and maintained in a state midway between pronation and supination. For this purpose, the ends of the splints should be shaped somewhat like the handle of a pistol, as this arrangement will afford an opportunity of bearing upon the radius in such a manner as to force the lower fragment outwards in contact with the superior, thereby counteracting the tendency above alluded to. If this point be strictly attended to, the cure can hardly fail to be perfect. Ordinarily, consolidation may be looked for in four weeks.

2. *Superior Extremity.*—This bone is occasionally broken at its superior extremity, the fracture detaching its rounded head, or extending through its neck. It is very rarely that the bone gives way at the bicipital tubercle. A comminuted fracture is not uncommon, and the injury is then often, if indeed not generally, complicated with fracture of the humerus and serious lesion of the elbow-joint. The accident could hardly be produced in any other way than by direct violence. Owing to the manner in which the parts are enveloped by the muscles, the diagnosis is usually very difficult.

The ordinary symptoms are, deformity just below the elbow-joint, caused by the flattening of the muscular prominence in that situation ; the projection of the upper end of the lower fragment in front of the limb, being drawn thither by the two-headed flexor muscle ; impossibility of executing the functions of rotation ; and the rapid supervention of severe swelling. To render the diagnosis certain, the best plan is to grasp the head of the radius with the thumb and index finger of one hand, and to rotate the forearm with the other. If there be a fracture, its existence will be rendered evident by the head of the bone refusing to obey the motions of the inferior fragment. By adopting this manœuvre, it will hardly be possible to mistake the nature of the case, unless there is so much swelling as to prevent the bone from being felt, in which event the examination must be repeated as soon as the tumefaction has measurably subsided.

In the treatment of fracture in this situation, the limb is placed at a right angle with the arm, in a state midway between pronation and supination, and the same splints are employed as in fracture of both bones of the forearm, care being taken to extend them as high up as possible, in order that they may afford adequate support to the upper fragment. When there is great disposition in the pronator muscle to draw the lower fragment over towards the interosseous space it should be counteracted by a compress.

The annexed drawing, fig. 490, from a preparation in my collection, exhibits a rare form of fracture, in which a portion of the head of the radius has been chipped off, and permanently united to the contiguous border of the coronoid process of the ulna. The specimen was obtained in the dissecting-room, and, therefore, nothing is known of its history.

Inferior Extremity.—The frequency of fracture of the lower extremity of the radius, its liability to be confounded with dislocation of the wrist-joint, and the imperfect recovery

of the functions of the hand which so often follows it, sufficiently attest the importance of the subject, and afford a satisfactory reason for the extraordinary attention that has been accorded to it by modern surgeons. Its literature is voluminous. Among those who have particularly interested themselves in its elucidation may be mentioned Colles, Dupuytren, Goyrand, Diday, Barton, Voillemier, Robert Smith, Busch, Lecomte, Callender, Gordon, Levis, Moore, Wight, Pilcher, Cruce, and Packard. In 1838 Dr. John Rhea Barton described a fracture of the radius involving the wrist-joint, but the existence of which was never, until recently, verified by dissection. The particulars of one such case have been reported by Dr. Butler, of Brooklyn, and of another by Lenoir, of Paris. In 1814 Mr. Colles, of Dublin, gave an account of a fracture which he had repeatedly witnessed at the distance of about one inch and a half above the articulation, and within the last ten years the whole question has been examined anew by some of the French, German, English, and American surgeons, especially the latter, who have contributed valuable suggestions in regard to its mechanism, diagnosis, and treatment.

Fig. 490.

Fracture of the Head of the Radius.

Two circumstances powerfully contribute to the production of this fracture, namely, the large amount of spongy substance in the inferior extremity of this bone, and the peculiarity of its connection with the wrist-joint. The relative quantity of this matter in its lower and middle portions, and also the difference in their compact structure, are very striking. These appearances, which are sufficiently conspicuous even in young subjects, are remarkably prominent in elderly persons, in whom the spongy substance of this part of the bone is generally exceedingly rarefied and infiltrated with oily matter, while the compact is often merely a thin crust, hardly as thick as an egg-shell, and scarcely less brittle. The singular mechanism of the wrist-joint cannot fail to arrest the attention of the surgeon. From the intimate manner in which the radius is articulated with the scaphoid and semilunar bones, any shock received upon the palm of the hand is readily communicated to it, causing it, if the force is at all severe, to give way under its influence; whereas the ulna, which has no such close relation, generally escapes injury.

Fracture of the lower extremity of the radius is most common in elderly subjects, for the reason already stated that this bone is remarkably brittle in advanced life. Young and middle aged persons seldom suffer from it. In children diastasis generally takes the place of fracture. The occurrence is comparatively rare in men.

Respecting the site, direction, and extent of fracture, the greatest possible diversity exists. While in some cases it is within three or four lines of the joint, in others, and these constitute the great majority, it ranges from a half to three-quarters of an inch or even an inch. In what is known as Colles's fracture, the distance is generally estimated at an inch and a half. Occasionally the fracture extends into the joint; and in very rare instances a portion of the articular surface, representing its posterior border, is chipped off, with or without the styloid process. A multiple fracture is by no means uncommon both above and within the joint. In the annexed drawing, fig. 491, from a preparation in the New York Hospital, there are four fragments, and in several cases I have met with five and even six. Occasionally, in fact, the end of the bone is literally ground into pieces. Fig. 492, from a specimen in the Pennsylvania Hospital, kindly lent me by Dr. Longstreth, represents a common form of fracture, both in site and direction, of this portion of the radius.

The *direction* of the fracture is, doubtless, as asserted by Voillemier, Malgaigne, Nélaton, Robert Smith, Levis, and others, for the most part transverse or nearly so, the line of fracture extending either directly from before backwards, across the bone, or from before backwards, and from below upwards, so as to render the posterior surface of the lower fragment considerably higher behind than in front. Cases, however, unquestionably occur, and that not un-

Fig. 491.

Multiple Fracture of the lower Extremity of the Radius.

frequently, in which the fracture is more or less, if not very decidedly, oblique.   Goyrand, who, in 1832, published an admirable memoir on injuries of this kind, broadly asserts that this is uniformly the case, and he has adduced an analysis of 47 cases in illustration of his position.   Whatever the direction may be, the edges of the fragments are nearly always

Fig. 492.
Simple Fracture of the Inferior Extremity of the Radius.

more or less irregular, roughened, notched, serrated, or denticulated.   An impacted fracture is occasionally seen, the most common form being that in which the end of the superior fragment is driven into the cancellated structure of the inferior.   When the force causing the impaction is very great the inferior fragment may literally be crushed by the superior. A double penetration is occasionally observed.   When the interlocking is very firm much difficulty may be experienced in effecting separation and in restoring the parts to their natural relations.

Not a little diversity of sentiment has been expressed by observers respecting impaction in this fracture.   While some actually deny the possibility of its occurrence, others equally entitled to credit do not hesitate to declare that it is very frequent.   Voillemier asserts that impaction is always present, the upper extremity being forcibly impelled into the lower, and he has adduced proof going to show that the impaction is occasionally double, the upper fragment being driven into the lower, and the latter into the former. Nélaton, basing his opinion upon a series of experiments performed upon the dead subject, shares this view.   I have myself no doubt of the occasional existence of impaction: the very mechanism, in fact, of the fracture, or the manner in which it occurs, is sufficient to prove this.   That it is frequent or constant is not true.

Luxation of the ulna is not uncommon in this fracture.   Moore, indeed, thinks that it is present in one half of the cases; but this is probably too high an estimate.   Fracture of the styloid process of this bone nearly always exists in the more severe forms of the accident, especially when the force is received upon the palm and on the inner margin of the hand.   Fracture of the lower extremity of the ulna is then not uncommon.   Displacement, if not actual rupture, of the flexor muscles of the carpus is an occasional occurrence. The carpal ligaments and the interarticular cartilage also not unfrequently sustain serious injury, the latter being sometimes wrenched from its bed.   Finally, the instances are not uncommon in which the radius is broken on both sides, especially in falls from a considerable height in which both arms are outstretched to break the force of the blow.

The accident nearly always results from a fall upon the open hand, in which the patient, stretching out the limb, receives the shock upon the palm, whence it is transmitted to the inferior extremity of the radius.   When the force is expended upon the palm and the ulnar margin of the hand, there will be likely to be, as a serious complication, a luxation of the ulna, either alone or in union with fracture of the styloid process of that bone.   Fracture of the styloid process of the radius will be a probable occurrence, if much of the weight of the body be thrown upon the palm and thenar eminence, or the palm and the thumb. Occasionally, the fracture is caused by a fall upon the back of the hand, or by direct violence, as the passage of the wheel of a carriage.

Fracture in this situation may be complicated, first, with fracture of the styloid process of the ulna, or of the head and shaft of that bone; secondly, with dislocation of the wrist-joint; and, thirdly, with serious injury of the soft parts.   In the case of a young man whom I attended along with Dr. Chenowith, the lower extremity of the radius was split in two by a transverse and an oblique fissure, the larger fragment being completely de-

tached, and thrown forwards and inwards over the ulna, whence, as it was impossible to replace it, I removed it by incision. A good recovery took place, with hardly any impairment of the functions of the wrist-joint. In my private collection is a specimen of transverse fracture of the radius, extending into the joint, and detaching the head of the bone by several small, vertical fissures. In this case I had an opportunity of dissecting the parts after the removal of the forearm, above its middle, by another surgeon, several weeks after the accident. The hand and wrist were much swollen, and infiltrated with pus, which was also freely diffused through the sheaths of the flexor tendons, while the connective tissue along the inner part of the palm contained a good deal of blood. The joint was filled with matter, and the scaphoid and semilunar bones, as well as the ulna, which was dislocated backwards, were almost completely divested of cartilage.

Among the most conspicuous *symptoms* of this fracture is the singular deformity of the hand, giving the limb the appearance of a dislocation of the wrist-joint, as exhibited in fig. 493, or an appearance not unlike the back of a silver fork. This is owing either to the impaction of the upper fragment into the lower, or to the fact that the lower fragment, along with the carpus, is drawn upwards and backwards, from an inch to an inch and a half above the joint, by the force of the injury, or by the continual agency of this force, and of the action of the extensor muscles of

Fig. 493.
Fracture of the lower Extremity of the Radius.

the thumb, while the upper fragment forms a slight projection on the palmar aspect of the forearm. Immediately above the posterior prominence is a well-marked depression which gradually slopes off towards the ulna, and is generally sufficiently large to receive the little finger. These appearances are always very striking when the limb is held in a situation midway between pronation and supination, and are easily effaced by extension and counterextension, although they are promptly reproduced when these forces are relaxed. The lower extremity of the forearm has a rounded form, from the increase of its antero-posterior diameter; the fingers are usually flexed, and the patient is unable to supinate the hand, which is, moreover, completely powerless; the pain is excessive, and considerable swelling soon arises, especially along the palmar aspect of the limb. Crepitation, except in case of impaction, may commonly be readily detected by rotating the hand upon the lower part of the forearm while the thumb and forefinger of the surgeon are applied just above the wrist-joint. Some surgeons assert that crepitation is never present; this is an error.

Instead of being thrown backwards, the inferior fragment is sometimes forced in the opposite direction, forming a projection in front of the forearm, beneath the flexor tendons. Another tumor, more conspicuous, and consisting of the lower extremity of the superior fragment of the radius, occupies the dorsal surface; it extends across the entire breadth of the limb, and is bounded above by a well-marked furrow, more distinct internally than externally. The accident, which is exceedingly rare, closely simulates dislocation of the carpus forwards, but may readily be distinguished from it by the presence of crepitation, and the facility with which the symptoms may be temporarily effaced under slight manipulation.

Fracture of the inferior extremity of the radius is, perhaps, most frequently liable to be mistaken than fracture of any other bone. The accident with which it is most liable to be confounded is dislocation of the wrist-joint, but from this it can always be easily distinguished by a careful examination and by the fact that a luxation here is one of the rarest of occurrences, while fracture, especially in women and in advanced life, is one of the most common. The singular deformity of the hand is absolutely characteristic, for there is no other accident which precisely resembles it. Crepitation, too, is always easily elicited by grasping the patient's hand and steadying the forearm near its middle, while the radius at the wrist is rotated upon its axis. The deformity is always easily effaced by extension and counterextension, but is immediately followed by recurrence when these forces are relaxed.

The adjoining sketch, fig. 494, represents a fracture of the inferior extremity of the radius, complicated with luxation of the ulna. The signs of both injuries are characteristic. The drawing was taken from a private patient.

The *prognosis* of this fracture is greatly influenced by the nature of the case and the manner in which it is managed. In any event, however, it must, even in its more simple forms, be regarded as a serious accident, often followed, despite the best directed efforts of the surgeon, by permanent deformity and impairment of the functions of the wrist-joint. Although complete consolidation ordinarily occurs in from four to five weeks, several months—commonly from three to six—elapse before the patient regains a good use of his hand and fingers, owing to the remarkable tendency, in all such injuries, in the resulting inflammation to extend to the synovial membrane of the digital articulations, and of the sheaths of the tendons. If the fracture is compound, comminuted, or involves the wrist joint, the danger of permanent impairment of function will be especially imminent. These facts should always be carefully explained to the patient at an early stage of the treatment, otherwise the surgeon may be unjustly censured for what cannot possibly be avoided. Of 92 cases of fracture of the inferior third of the radius, referred to by Professor Hamilton, only 26 are positively known to have left no perceptible deformity or stiffness about the wrist-joint. The adjoining cut, fig. 495, from a specimen in my collection, exhibits a very common species of deformity in badly treated fractures of this portion of the radius. The injury was accompanied by fracture of the styloid process of the ulna. The whole hand is drawn over towards the radial border of the wrist.

Fig. 494.

Fracture of the Lower End of the Radius.

Among the various contrivances that are before the profession for the *treatment* of these fractures, that of Dr. Levis is, perhaps,

Fig. 495.
An Old Fracture of the Inferior Extremity of the Radius attended with Separation of the Styloid Process of the Ulna.

the very best and most reliable. That of Dr. Gordon, of Belfast, is also a very superior article, as it admirably fulfils all the indications presented in such lesions. The splints invented by Dr. E. H. Coover, of Harrisburg, Dr. Henry C. Hewit, of New York, and Dr. Carr, of Boston, also merit favorable mention. Dr. Moore's dressing is very simple and effective; and excellent cures, as I know from personal experience, may be obtained from the use of the apparatus of Dr. Thomas Bond, so long in vogue among Philadelphia surgeons. The pistol-shaped splint, said to have been devised by Nelaton, possesses few of the requisites necessary for the successful management of fractures of the inferior extremity of this bone, although Erichsen declares that he has always had excellent results from it. The splint of Dr. Levis, fig. 496, is made of copper, coated with tin to prevent oxidation; it is very thin and flexible, to adapt it to the peculiarities of the size and form of the forearm, ends in a curve in front to receive the palm of the hand, and has a series of little elevations along its edges to keep the bandage used in confining it from slipping. A layer of wadding or flannel serves as a lining; no dorsal splint is required, but in most cases a pad should be placed over the back of the wrist to guard against displacement of the lower fragment. The thumb and fingers are left free, while the anterior extremity of the splint, following accurately the radial curvature, fixes the thenar and hypothenar eminences of the hand in their moulded beds. Fig. 497, shows the manner in which the splint grasps the limb before the application of the roller.

The apparatus of Dr. Bond consists, as shown in figs. 498 and 499, of two splints, one of medium-sized binder's board, and the other of thin, light wood, furnished with a block

Fig. 496.
Levis's Splint.

Fig. 497.
Levis's Splint Applied.

and edges of thin sole-leather, about an inch in height, the whole presenting somewhat the appearance of a shallow trough. They are long enough to reach from a short distance below the elbow to within an inch of the knuckles of the metacarpal bones, the block of the latter resting in the hollow of the palm, and both being well padded with wadding. They are fastened in the usual manner. When there is any marked tendency to displacement, a narrow, square compress, not more than a third of an inch in thickness, may be laid over the projecting fragment, to give greater concentration and effect to the pressure of the apparatus opposite the seat of fracture. Sometimes it is found

Fig. 498.

Bond's splint, for the Back of the Forearm.

Fig. 499.

Bond's Splint, for the Front of the Forearm and Hand.

necessary to use a compress on each side of the wrist; but such is the accuracy with which the palmar splint fits the parts that this portion of the dressing may generally be dispensed with. There is no use, in any case, of an interosseous compress, as there is never any tendency in the fragments to inward displacement. The advantage of the apparatus of Dr. Bond is, as in those of Levis and Gordon, that, while it maintains the thumb perfectly at rest, and, consequently, prevents its extensor muscles from disturbing the fragments, the fingers may be freely moved in front of the block; a circumstance of no trifling importance in an accident so liable to be followed by inflammation and adhesions of the sheaths of the tendons, and ankylosis of the thumb and fingers.

In Gordon's mode of dressing these fractures, the forearm is placed in the prone position, and is supported by a splint, which, to use the inventor's own language, "consists of the body, the ulnar, and bevelled portions, with a curved back splint, fig. 500. The lower end of the ulnar portion is curved forwards and hollowed to receive the inner border of the flexed hand, with a slit for the carpal strap. The bevelled portion is secured

Fig. 500.

Gordon's Splint for Colles's Fracture.

Fig. 501.
Gordon's Splint Applied.

to the body of the splint nearly half an inch internal to its margin; it is cut off obliquely from without inwards and from below upwards; it is applied to the palmar surface of the upper fragment, which it is its office to fix. The lower end of the back splint is much curved forwards. This curve, with a thick pad, is necessary to enable it to press the base of the metacarpus, the carpus, and the lower end of the lower fragment well forwards for the restoration of the natural aspect of the carpal surface and the concavity of the radius." The dressing is confined with three wide straps, not with a roller, and the forearm is well supported by a sling; when the fracture is only a short distance above the joint, the lower strap is passed over the back of the splint and over the carpus when it is higher up, as in Colles's fracture. Fig. 501, shows the application of the apparatus and the position of the limb.

The dressing of Dr. Moore, fig. 502, consists of a compress from one-half to three-quarters of an inch in diameter and two inches in length, which, after the reduction of the fracture, is placed under the ulna, abutting against the pisiform bone and slowly displacing the thumb, and while the parts are held in position, is confined with a strip of

Fig. 502.

Moore's Method of Treatment. 1. A Cylindrical Compress; 2. Bandage of Adhesive Plaster; 3. Line of Cut in Plaster six hours after the reduction.

adhesive plaster, of similar width, and drawn forcibly around the wrist, its distal edge being brought around on a line with the end of the radius. The operation is completed by suspending the arm in a sling, three inches wide, and so arranged as to bear exclusively on the dressing. The hand is brought down and allowed to hang naturally, its weight and that of the forearm being used to press the ulna upwards into its proper place. Motion of the wrist-joint is counteracted, if necessary, by a light splint stretched along the dorsal surface of the limb. The dressing, which is applied very tightly in the first instance, is relaxed at the end of six hours by thrusting one blade of a pair of scissors underneath it on the back of the wrist, dividing it completely. Dr. Moore's treatment is simplicity itself, and its efficiency has been attested by several eminent American practitioners, among others by Dr. Prince, of Illinois.

Good results may be secured in the treatment of these fractures with two straight splints, extending from near the elbow as far forward as the knuckles of the fingers, the

anterior one being well padded in the part corresponding with the palm of the hand. Compresses should be applied over the seat of the fracture both in front and behind, and the thumb should be made to look directly upward, while the fingers are left unincumbered. In applying the bandage the hand should be slightly inclined toward the ulna. Dr. Barton always obtained excellent cures by the use of two straight splints reaching forward to the ends of the fingers. His plan was to make passive motion at a very early period after the accident.

Whatever splint or apparatus may be used, the cardinal point is to effect thorough reduction of the fracture, by extension and counterextension on the hand and forearm, while the hand is inclined towards its ulnar margin, and pressure is made at the seat of the fracture, so as to force or draw the ends of the fragments into their proper positions. To accomplish this, great difficulty will often be experienced, expecially when the fracture is impacted, comminuted, or associated with luxation of the lower end of the ulna; under such circumstances, indeed, very considerable force is often required to restore the symmetry of the limb. The tendency to displacement, which, however, is seldom great, and often entirely absent, generally ceases of its own accord in five or six days, the muscles becoming, so to speak, reconciled to their new relations. Meanwhile any disposition of the kind must be counteracted by strict attention to the dressings. In children reduction is generally easily effected and maintained. The splints need not be retained, in the adult, longer than five weeks, or four weeks in young subjects. Stiffness of the fingers will not be likely to occur if the movements of their joints be properly attended to during the earlier stages of the treatment.

The treatment of fracture of the inferior extremity of the radius, suggested by Dr. John Swinburne, is very simple and effective. It consists in confining the forearm upon a single splint, stretched along its posterior aspect from the elbow to the metacarpophalangeal joints, and composed of a thin piece of wood of the width of the limb, and provided with two compresses, one of which fills up the concavity of the carpus, while the other supplies the deficiency in the straight line of the arm above. The splint is secured with adhesive strips, the application of which is commenced at the elbow, and continued, at intervals of several inches, down the limb to the hand, which, the displaced parts having previously been adjusted, is then firmly fastened, in such a manner as to allow perfect freedom to the thumb and fingers. Additional support may be given, if necessary, with an ordinary roller. The annexed cuts, figs. 503, 504, and 505, afford a good idea of the apparatus and of the appearance of the limb after its application.

The above dressings answer equally well, whatever may be the character of the displacement, whether backwards or forwards. Passive motion is instituted at the end of three weeks, proper support being given to the fracture while this is being made. The operation is afterwards repeated every other day, until the end of the fifth week, when the apparatus may generally be discontinued, the bandage alone being used. If the joints of the fingers are stiffened, they should receive special attention at each dressing. I have met with cases in which bandaging, douching, and pressure were obliged to be continued daily for many months before the affected joints regained their full motion.

Finally, the radius, in young subjects, occasionally gives way at the lower *epiphysis.* The accident is uncommon, but a number of cases, showing the possibility of its occurrence, are scattered through the records of surgery, and several have come under my personal observation. Voillemier, in experimenting upon the dead body, produced separation at the epiphysis with great facility, simply by forcible flexion or extension of the wrist, not only in young subjects, but, in one instance, in a stout, robust man of twenty-four.

Fig. 503.

Fig. 504.

Fig. 505.

Swinburne's Apparatus for Fracture of the Radius.

The injury, however induced, is managed upon the same general principles as an ordinary fracture of the radius, from which it is not always easy to distinguish it.

FRACTURES OF THE HUMERUS.

Fractures of the humerus are of frequent occurrence, and are of great practical importance, from the difficulty which so often attends their diagnosis and treatment. They may take place in the shaft of the bone, at its surgical neck, at its head within the capsular ligament, and at its condyles.

1. *Shaft.*—The simplest fractures of the humerus are those which occur in its shaft, as they are most easily detected and treated, and least liable to be followed by deformity and loss of function. Caused occasionally by direct violence, they more frequently result from falls upon the palm of the hand, in attempts to save the body from more serious injury. In several instances that have come under my observation, and which are alluded to in another part of this section, the accident was produced by muscular contraction ; in one case, while the patient was in the act of throwing a chip. The fracture is usually oblique, a transverse one, properly so termed, being exceedingly uncommon. A complicated fracture of the shaft of the humerus is occasionally met with, as a consequence of the explosion of firearms, the contact of machinery, or the passage of the wheel of a carriage.

The symptoms of fracture of the humerus in this situation are usually characteristic, the deformity, preternatural mobility, and crepitation being well marked. In general, there is some shortening, the amount varying according to the obliquity of the fracture and the size of the limb ; in ordinary cases it is very slight, the weight of the arm being sufficient to counteract the action of the muscles, at least to a considerable extent. The direction of the displacement is regulated by the line of fracture ; if this be below the insertion of the deltoid, the inferior fragment will be drawn inwards, but outwards if it be above that point. However this may be, any deformity that is present is easily effaced by extension and counterextension. The limb is completely powerless, and is always supported by the patient at the wrist.

The treatment of this fracture is very simple, the only apparatus necessary being two splints, and a roller applied from the fingers up. The splints may consist of two stout pieces of unoiled sole-leather, felt, or binder's board soaked in hot water, and accurately moulded to the shape of the limb ; one extending from the axilla to within an inch of the internal condyle, and the other from the shoulder-joint to the corresponding point of the outer condyle, the two, when applied, nearly meeting each other. The forearm and hand are well supported in a sling ; and, for the sake of greater security, the arm may be fastened by a few turns of a bandage to the side of the trunk. Special care is taken not to raise the elbow, as a certain degree of weight is necessary to prevent overlapping of the fragments.

This apparatus may be advantageously replaced at the end of a week, or as soon as the swelling consequent upon the fracture has measurably subsided, by the immovable dressing. If the tendency to overlapping of the fragments is uncommonly great, a weight, as a few pounds of shot, may be temporarily suspended from the elbow, which, under all circumstances, must be left free. If the dressing be properly applied there is no reason for supporting the forearm with splints, as is urged by Boyer and some other surgeons, in order, as is alleged, to place the brachial muscles in a quiescent condition, and thereby counteract any tendency to displacement. Such a precaution, however, is wise, and cannot be too strenuously insisted upon, when the fracture affects the lower portion of the shaft of the bone, an accident in which there is always unusual danger of overlapping, if the parts be not thoroughly supported and carefully guarded. It is in this portion of the bone in which, if the treatment be not most cautiously conducted, want of union is so liable to occur.

In simple fractures of the shaft of the humerus union may usually be expected by the end of the fifth week. Injuries of this kind are generally readily repaired even in very old persons. Cases are recorded in which consolidation occurred within the ordinary limits at seventy-five, eighty-nine, and even one hundred years, as in an instance observed by Dr. W. W. Dale, of Pennsylvania.

Fractures of the shaft of the humerus are occasionally followed by " wrist drop," dependent upon imprisonment and compression of the musculo-spiral nerve by the callus at the seat of the injury. Two cases of this occurrence have fallen under my observation ; one in a patient of my own, and the other in an out-door patient at the College Hospital. The only remedy is the removal of the offending callus.

2. *Inferior Extremity.*—Fracture of the condyles may be caused by a fall upon the point of the elbow, by a blow, or by the passage of the wheel of a carriage. I have repeatedly known it to be produced by a fall upon the palm of the hand, the limb being at the time in an extended position. The accident may be simple, or, as not unfrequently happens, complicated with serious mischief to the joint and soft parts. Both condyles may be broken, as in fig. 506, or one only may be affected. In the former case, a longitudinal fracture usually extends some distance along the centre of the bone, and then terminates, probably an inch and a half to two inches above the joint, in an oblique or transverse fissure in the lower portion of the shaft of the humerus, thus producing three fragments. Not unfrequently, however, there is a separation merely of one of these prominences, the fracture being then usually directed obliquely downwards into the joint. In a third series of cases, the small projection, the internal epicondyle as it is termed, is broken off, either obliquely or perpendicularly, without any involvement whatever of the articulation.

Fig. 506.

Fracture of the Condyles of the Humerus.

Fracture of the condyles, especially when it affects only one of these prominences, is almost invariably an accident of early life, the great majority of cases occurring before the fifteenth year. Occasionally an instance is met with in old age, in consequence of the inordinate brittleness of the osseous tissue.

The symptoms of fracture of this portion of the humerus vary according to circumstances, as might be expected from a consideration of the structures of the elbow-joint. When both condyles are severed just above the articulation, the radius and ulna project backwards, a hollow exists at the bend of the arm, the forearm is slightly flexed, and the distance between the elbow and wrist is sensibly diminished. When the fracture involves both the condyles and the inferior extremity of the shaft of the bone, there will be, in addition to these phenomena, an increase in the width of the bend of the arm, and an appearance of greater flattening. The accident, whether accompanied by this occurrence or not, is liable to be mistaken for dislocation of the radius and ulna backwards; but the diagnosis may generally be readily determined by the fact that the symptoms which mark the former lesion promptly disappear on extending the limb, and that crepitation may be produced when the forearm is rolled upon the humerus.

Fig. 507.

Fracture of the Internal Condyle.

When the inner condyle alone is detached, as in fig. 507, the ulna projects backwards, but resumes its natural position on extending the limb; the condyle forms a tumor at the back part of the elbow; crepitation is perceived on bending the forearm; and, if the forearm be extended, the humerus will advance in front of the ulna as the latter recedes.

Fracture of the external condyle, fig. 508, is characterized by the existence of a tumor at the outer and back part of the elbow, by crepitation on rotating the radius, by the supine position of the hand, by the inability to move the joint, and by the constant semiflexion of the forearm.

Fig. 508.

Fracture of the External Condyle.

Whatever may be the nature or extent of these fractures in the vicinity of the elbow-joint, there is always severe pain, with complete inability to move the limb. Considerable swelling soon follows, and effusion rapidly takes place within the articulation, obscuring the characteristic features of the injury, and rendering the diagnosis proportionately difficult. When such a condition exists, leeches, fomentations, and other antiphlogistic measures may be necessary before the parts will be sufficiently tolerant of the requisite manipulation.

The inferior extremity of the humerus occasionally gives way just above the condyles, generally in a more or less oblique direction, as seen in fig. 509. Such an occurrence may, unless great care be taken, be readily confounded with dislocation of the ulna and

Fig. 509.

Fracture of the Lower End of the Humerus.

radius backwards, which its symptoms, at first sight, closely resemble. The signs of distinction are the mobility of the limb and the facility with which the parts can be restored to their natural position, followed by the immediate return of deformity upon discontinuing the extension. The accident, which should be treated on the same principles as fracture of the shaft of the humerus, is extremely liable to be succeeded by stiffness of the joint.

In children, prior to the completion of the ossific process, there is sometimes a separation of the *epiphysis* of the inferior extremity of the humerus, induced by falls upon the hand or elbow. The symptoms resemble those of fracture in this situation in the adult, there being an unnatural projection at the back of the joint, caused by the retraction of the lower fragment along with the bones of the forearm, and the ready production of crepitation on extending the limb. The accident is treated as if it were a fracture.

Fractures of the inferior extremity of the humerus, involving the elbow-joint, are peculiarly liable to be followed by severe inflammation of the synovial membrane, extensive effusion, ankylosis, and deformity. Even in the more simple forms of these injuries, where the treatment is most skilfully conducted, there is generally great risk of an unfavorable result, and in any event a long time must elapse before there will be a good use of the articulation. A prudent surgeon should, therefore, at once inform his patient of the nature and probable consequences of the case. From five to six weeks is the average period necessary for the reunion, which, unless the apposition is most perfect, will occasionally be fibro-cartilaginous instead of osseous.

Fig. 510.
Badly-treated Fracture of the External Condyle of the Humerus.

The nature of the deformity, in badly-treated fracture of the condyles of the humerus, may exhibit itself in a variety of ways, depending upon the peculiar mode of management. Sometimes a posterior projection remains, caused by the backward displacement of the lower end of the bone; not unfrequently the limb has a strangely twisted appearance, either in the direction of pronation or supination; occasionally it is permanently flexed or extended; and sometimes, again, it is greatly increased in breadth. A very common form of badly-treated fracture of the external condyle is exhibited in fig. 510, from a clinical case.

Most practitioners are agreed upon the propriety of treating these fractures with the forearm in the rectangular position. There are but few that pursue the opposite plan, and the arguments that have been adduced in its favor have by no means convinced me that it is at all equal to the ordinary method. To maintain the limb in the flexed position, I have long been in the habit of employing a light, well-shaped tin case, extending from the axilla to the metacarpo-phalangeal articulations. This, being properly lined with wadding, affords an admirable support to the limb, and effectually prevents displacement of the fragments, whatever may be their size or number. The skin over the inner condyle must be well protected from pressure, otherwise it may become seriously inflamed, if not ulcerated. To obviate this occurrence, a small gap should be made in the apparatus for its special accommodation. A case made of India-rubber, felt, thin wire, sole-leather, or plaster of Paris answers quite as well as one of tin, and is even, in some respects,

superior to it, inasmuch as it admits of more accurate adaptation to the irregularities of the limb. The forearm is supported in a sling, in a state midway between supination and pronation.

The rectangular splint, originally recommended in the treatment of these fractures by Physick, is still capable, when judiciously used, of rendering good service in this class of cases. The best contrivance of the kind, however, is that of Professor Agnew, in which the two pieces are united by hinges, thus permitting the angle of flexion to be regulated at pleasure. There is some diversity of opinion as to whether the splint should be applied to the outside or inside of the limb. My own experience is that the advantages are decidedly in favor of the latter, provided an opening be left at the elbow for the accommodation of the epicondyle, which should always be carefully protected from harm, whatever apparatus be employed. Excellent cures may be effected, especially in young children, by applying the splint in front of the limb, so as to concentrate the pressure at the seat of the fracture.

Dr. Oscar H. Allis, of the Presbyterian Hospital of this city, recently called attention to the importance of treating fractures of the lower extremity of the humerus in the extended position. Having enjoyed uncommon facilities for the study of injuries of this kind, he is convinced that much better cures can be effected in this than in any other way. The inflammation consequent upon the accident having been reduced, suitable means, as a splint of felt, binder's board, or unoiled sole leather is moulded to the anterior surface of the arm and forearm, and confined by means of the egg-paste dressing, the bend of the elbow having been previously well covered in with cotton or some other soft material. Three layers of bandage are generally amply sufficient. The extended position is maintained until complete consolidation has taken place, usually from three to four weeks and a half, according to the age of the patient, when a more convenient position is assumed, and the limb carried in a sling, passive motion being now for the first time attempted. Dr. Allis assures me that his success with this treatment, extending over many years, has been most gratifying, and he has adduced a number of cases, going to show that the deformity of the limb, illustrated in fig. 510, is a very common occurrence when fractures of the condyles of the humerus are treated with the forearm in the flexed position, but may be readily prevented in the extended.

Fracture of the tubercle of the internal condyle—the so-called *epicondyle* of the French anatomists—is by no means a rare occurrence, especially in very young children, and is generally caused by direct injury, as a fall or blow upon the elbow. Prior to the completion of the ossific process, it is sometimes occasioned by sudden and violent muscular contraction. The direction of the fracture is usually more or less oblique. Not unfrequently the lesion is complicated with dislocation of the radius and ulna upwards, or with fracture of the inner condyle. When it exists as an independent affection, it does not, of course, extend into the joint, although it is liable, even then, unless properly treated, to be followed by ankylosis.

Fig. 511.

Fracture of the Epicondyle.

The diagnosis is readily established by the great mobility of the fragment, represented by the epicondyle, by the easy production of crepitation, and by the other ordinary signs of fracture. The fragment either retains its natural position, or, as is more generally the case, it is pulled down a short distance over the forearm, occasionally almost in a straight line, but more commonly to one side, by the action of the flexor muscles. The movements of the joint are more or less impaired, and, when the accident has been caused by external violence, there is often a considerable amount of ecchymosis.

Although the small fragment may generally be readily restored to its normal position, great difficulty is experienced in keeping it there until it has regained its former attachments. For this reason it is always well to give a guarded prognosis, as few cases recover without a certain degree of deformity or even ankylosis.

The treatment is by the rectangular case, with an opening opposite the inner condyle to ward off pressure, the limb being carefully bandaged from the fingers up, and the epicondyle confined by adhesive strips and compresses. Passive motion must be commenced at the end of a month, and afterwards repeated daily until all danger of ankylosis is over. Now and then the cure is best effected with the limb treated in the straight position.

No example, of a reliable character, of fracture of the external epicondyle has ever been recorded. Indeed, the very possibility of such an occurrence is generally denied, surgeons in the most extensive practice having never met with any cases of it.

There are no fractures which require more constant vigilance after their adjustment

than those about the elbow-joint. The dressings should, therefore, during the first week, be frequently examined, in order that they may be promptly changed in the event of their being either too tight or too slack, and special pains must be taken that the bandage, in the first instance, be applied rather loosely, due allowance being always made for the resulting swelling. As a general rule, the best plan is to reduce the inflammation consequent upon the injury, as a preliminary step, by placing the limb in the extended position upon a pillow, and keeping the parts constantly wet with a strong solution of lead and opium. The first five or six days may generally be well spent in this manner. Passive motion should not be instituted until complete union is obtained, after which it should be repeated, at first every other day, and then daily, until all danger of ankylosis is over. At this stage, too, it is highly important that the limb should be released from the constrained position which it occupied during the treatment, being gradually extended if it was flexed, and flexed if it was extended.

Fractures of the elbow are often of a *complicated* character, as in fig. 512, especially when caused by railway injury, or falls from a great height, penetrating the joint, exten-

Fig. 512.

Complicated Fracture of the Elbow.

sively lacerating the soft parts, and, perhaps, comminuting the bones. Such accidents are always fraught with danger, both to limb and life, and usually promptly require amputation. Even supposing that the limb could occasionally be saved under such circumstances, the patient's recovery will be extremely tardy, and when, at length, he does get well, it will be found, as a rule, that the joint will be worse than useless, only serving as a hindrance. Resection is sometimes admissible in these injuries; but, as a principle, amputation is altogether preferable, especially when they are accompanied by extensive laceration of the soft parts.

In the treatment of these fractures about the elbow great comfort is derived from placing the limb upon a pillow arranged along the patient's side; or, what often answers a better purpose, a Stromeyer's cushion, a triangular, wedge-shaped appliance, about fifteen inches in length by six inches in width, and four inches in thickness at its inferior extremity.

Fig. 513.

Stromeyer's Cushion, with Straps applied.

It is secured to the limb and to the neck by suitable straps, and to the body, if necessary, by several turns of a roller. Fig. 513, from Bryant, affords a good idea of this very excellent apparatus.

3. *Superior Extremity.*—The superior extremity of the humerus includes the hemispherical head of this bone and its two necks, the anatomical and surgical; the former being the narrow, constricted portion between the head and its tuberosities, and the latter all that portion which intervenes between these prominences and the insertion of the broad dorsal muscle, its length varying from an inch and a half to two inches, according to the stature of the individual.

a. *Fracture of the Head.*—Fracture of the head of the humerus is so extremely uncommon that its possibility was for a long time a matter of controversy among surgeons. The cases, however, that have been reported by Bichat, Astley Cooper, Dorsey, Gibson, R. W. Smith, Malgaigne, and others, have effectually dispelled all doubt upon the subject. I saw, myself, during my pupilage, in a patient of Dr. George McClellan, an instance of the kind, which had been mistaken by the attendants for a fracture of the acromion process, and the true nature of which was not detected until several years after the occurrence of the accident, when the man, who was upwards of forty years of age, died of disease of the liver. The fracture, as was shown on dissection, had extended obliquely from above downwards through the head of the bone; and, although it had become perfectly consolidated, there were several rough prominences which, while they unmistakably indicated the seat of the injury, greatly impeded the movements of the shoulder-joint. The accident had been caused by a fall from a carriage.

In a specimen in my private collection, obtained from the body of an insane woman, upwards of seventy years of age, whose skeleton had been broken in numerous places, in a fall from a second-story window, the head of the humerus is completely detached from the anatomical neck, the articulating surface, which retained its smooth and polished aspect, being tilted over the great tuberosity against the posterior surface of the bone, to which it is firmly and inseparably united by osseous matter, the fracture having evidently occurred a long time before death.

Directly opposite to the prominence thus formed, on the inner surface of the humerus, is another large projection, fully an inch in length, having the character of a stalactitic exostosis. The bicipital groove is completely effaced. The whole bone is extremely light, its weight being hardly two ounces and a half. The annexed cut,

Fig. 514.

Fracture with Detachment of the Head of the Humerus.

fig. 514, conveys a good idea of the distinguishing features of this remarkable, if not unique, specimen.

When the head of the humerus is completely detached from the tubercles along the anatomical neck, it must necessarily act as a foreign body, speedily perishing from the want of nourishment. In some cases, however, it is enabled to preserve its vitality, although imperfectly, by retaining its connection with the rest of the bone through the intervention of a few bands of fibrous tissue.

β. *Fracture of the Anatomical Neck.*— In old persons, the head of the bone, fig. 515, is sometimes not only broken off, but thrown down into the axilla, where it forms a distinct tumor that may easily be felt by the hand, but which does not obey the movements of the arm. Such an occurrence, which occasionally happens in the act of reducing a shoulder dislocation, always seriously complicates the case. The accident is generally caused by a fall on the elbow, or by violence applied directly to the shoulder, and is very liable to be mistaken for other injuries.

The intracapsular fracture of the humerus is occasionally impacted, the upper fragment being propelled into the inferior or conversely. The occurrence, which is extremely uncommon, is met with exclusively in old subjects, laboring under atro-

Fig. 515.   Fig. 516.

Fracture of the Anatomical Neck of the Humerus.

Fracture of the Anatomical Neck of the Humerus, in which the Head of the Bone is turned upside down.

phy and great fragility of the osseous tissue. The head of the bone can be felt in the glenoid cavity, there is a slight hollow below the acromion process, the axis of the arm is directed inwards towards the coracoid process, and the elbow is somewhat separated from the trunk. Crepitation is either very faint or entirely wanting. The length of the humerus is diminished, but generally in so slight a degree as to render it unavailing in a diagnostic point of view.

Fig. 516, from a specimen in my collection, represents an ancient fracture of the anatomical neck of the humerus, in which the head of the bone, united by a thick layer of osseous matter, is turned upside down, the centre of the articular surface corresponding with the outer border of the shaft. Several stalactites, one of large size, had been developed immediately below the head. The joint was of course completely annihilated. Such a case would have formed a proper subject for excision.

γ. *Fracture of the Surgical Neck.*— Fracture of this portion of the humerus is uncommon, but may take place from the same causes as fracture of the shaft of the bone, as a fall upon the hand or elbow, direct violence, or, although rarely, from muscular action. The injury is always attended with marked displacement, forming an important feature in its history. The superior fragment, yielding to the influence of the spinate muscles of the scapula, is generally drawn outwards and slightly backwards, while the inferior one is

directed inwards towards the side of the trunk by the pectoral, broad dorsal, and large teres muscles, attached to the inner border of the bicipital groove. At the same time that

Fig. 517.

Fracture of the Surgical Neck of the Humerus.

this portion of the humerus is dragged inwards, it is usually somewhat raised by the joint agency of the muscles that pass from the scapula to the forearm ; the extent of the displacement, however, is commonly trivial, inasmuch as the weight of the limb is almost sufficient to counteract its occurrence.

Fig. 518, from a specimen in my cabinet, affords a good illustration of a badly-treated fracture of the surgical neck of the humerus, followed by exuberant callus, as must always be the case when the ends of the fragments are not kept properly in place.

The diagnosis of these different fractures is not always so easy as might, at first, be supposed. Their character is often greatly obscured by the swelling, and the consequent

Fig. 518.

Badly United Fracture of the Surgical Neck of the Humerus with Exuberant Callus.

difficulty of making a thorough examination. In general, there is marked deformity at the shoulder-joint, the deltoid muscle is flattened, the arm is twisted upon its axis, and, if the injury is situated on the outside of the capsular ligament, there is usually slight shortening of the humerus, with distinct projection of the upper end of the lower fragment. If extension and counterextension be made, so as to draw the parts in place, crepitation may be elicited, followed by a recurrence of all the previous symptoms the moment the surgeon relinquishes his hold. In cases of doubt, the best plan is to grasp the head of the humerus firmly with the thumb and fingers of one hand, while with the other we seize the elbow and move the arm on its axis. If fracture be present, it will almost be sure to be detected by the crepitation produced by this manœuvre, whereas, if there be a dislocation, no noise will be perceived, and there will also be little or no mobility. When the head of the bone is fractured, and thrown off the glenoid cavity, the symptoms will be of a compound character, the crepitation and abnormal mobility coexisting with flattening of the deltoid muscle, extraordinary saliency of the acromion process, and a remarkable fulness in the axilla, caused by the presence of the displaced bone, at the same time that the upper extremity of the inferior fragment projects prominently upwards and inwards.

Treatment.—Fractures of the superior extremity of the humerus must all be treated upon the same general principles as fractures of the shaft of the bone. The limb being bandaged from the fingers up, two splints, broad and hollow, made of unoiled sole-leather, binder's board, gutta-percha, or gum sheeting, are applied, one on the outside and the other on the inside of the limb, the former being long enough to extend from the external con-

Fig. 519.

Welch's Shoulder Splint.

dyle to the top of the shoulder, which it should cover well, as in fig. 519, as it is designed to give firm support to the broken parts. The inner splint should be thickly padded at its superior extremity, otherwise it may chafe the skin or exert undue pressure upon the axillary vessels and nerves. No cushion will be required for the axilla. The arm is carefully secured to the side of the chest, and the forearm is supported in a sling, but the elbow is left free, in order that its weight may counteract the tendency to overlapping of the fragments. Passive motion is instituted at the end of the fourth week, and firm union may reasonably be expected in a fortnight more. A long time, however, will elapse before the joint will completely regain its functions, if, indeed, it ever do. Permanent lameness will be inevitable, if the fracture be intracapsular and comminuted, owing to the difficulty of readjusting the fragments.

When fracture of the superior extremity of the humerus is complicated with dislocation, the proper plan, of course, is to restore the displaced bone to its natural position before any attempt is made to adjust the ends of the fragments. The operation, however, will necessarily be one of extreme difficulty, on account of the shortness of the superior piece, which thus deprives the surgeon of the advantage of a suitable lever. His whole reliance must, therefore, be upon well-directed pressure and counter-

pressure, while the patient is fully under the influence of an anæsthetic, complete muscular relaxation being essential to success. When the operation fails, it has been recommended to let the dislocated head of the bone remain in its unnatural situation, and to bring the upper extremity of the lower fragment in contact with the glenoid cavity, in the hope that, in time, as the bone becomes rounded off, it will contribute to the restoration of the motion of the limb. Such an idea, however, it seems to me, must be perfectly delusive; for it is impossible, under such circumstances, for nature to make a good or useful joint. Instead, therefore, of pursuing such a practice, I should not hesitate, if a case of the kind were to present itself to me, to cut down upon the dislocated bone, and push it back into its natural position; or, if this be impracticable or deemed inexpedient, and the head of the bone be found to compress the axillary plexus of nerves, to perform excision.
Fractures of the surgical neck of the humerus are occasionally impacted, the upper extremity of the inferior fragment being forcibly driven into the cancellated structure of the superior, or conversely. Such an occurrence is most common in old subjects, after the age of fifty-five, in consequence of interstitial absorption of the osseous tissue, and may be produced either by a blow upon the shoulder, or, what is more common, by a fall upon the elbow. The extent of the impaction varies from a few lines to half an inch or more. As the bone retains its continuity, the symptoms of the accident are usually very obscure, there being neither mobility nor crepitation, unless the fragments are unlocked by being pulled forcibly asunder. Nevertheless, there is generally some deformity perceptible upon firmly grasping the humerus, and an alteration in the axis of the limb, which often looks as if it were twisted together with severe pain, and usually also more or less contusion of the soft parts. If the impaction is extensive, there will, in addition, be some degree of shortening of the arm, or a slight diminution in the distance between the shoulder and elbow. These circumstances, conjoined with the fact that the patient has received a severe injury, that there is loss of motion in the joint, and that all the symptoms of dislocation are absent, afford sufficient evidence of the probable nature of the case.

The impacted fracture requires no special treatment on its own account. To pull the fragments forcibly asunder would only produce mischief and trouble. Instead of such interference, the surgeon contents himself with supporting the limb, and combating inflammation by leeching, fomentations, and other means. In due time passive motion is instituted, lest ankylosis of the shoulder-joint should arise.

δ. *Great Tuberosity.*—Fracture of this portion of the humerus, although uncommon, is probably not as infrequent as is generally supposed, the obscurity of its symptoms rendering it extremely liable to be mistaken for other lesions in and around the scapulo-humeral articulation. The accident may occur at almost any period of life, except, perhaps, in early childhood, and is usually caused by a fall or blow upon the forepart of the shoulder, the force being concentrated upon the upper extremity of the humerus so as to separate the large tubercle from the hemispherical head and shaft of the bone. Pitha, Theden, and others, have met with cases in which the detachment was caused by the violent contraction of the two spinate and small teres muscles.

The existence of the fracture is denoted by considerable flattening of the deltoid muscle, by a remarkable increase in the width of the upper portion of the arm, which is nearly double what it is in the natural state, and by the presence of two osseous prominences, one of which, consisting of the detached tuberosity, is situated at the superior and outer part of the joint, and the other, formed by the head of the humerus, at the upper and inner part. The acromion is abnormally salient, and the arm is separated from the side, but may be approximated to it without difficulty, and readily rotated in every direction by the surgeon.

The diagnostic signs most worthy of reliance, are the great increase in the breadth of the articulation, the refusal of the thumb to sink into the glenoid cavity, as it always does in dislocation of the shoulder, the preservation of the length of the limb, and the production of crepitation upon rotating the humerus by seizing it just above the elbow while the surgeon encircles the head of the humerus with both hands. Another important evidence is that the deformity is readily effaced by manipulation, but instantly reappears when it ceases.

Repair, generally of an osseous character, is effected in from four to six weeks, according to the age of the patient, the immobility of the fragments, and the amount of the resulting inflammation, which is always very considerable from the contusion of the soft parts. The motions of the joint, in consequence, remain imperfect for many months; and in not a few cases, even when the greatest vigilance is exercised, they are never com-

pletely regained, owing to a redundancy of callus and the formation of osseous excrescences around the articular surfaces.

In the *treatment* of this fracture, one of the leading indications is to neutralize the action of the muscles which are attached to the tubercles of the humerus, the larger one receiving the insertion of the two spinate and the small teres, and the lesser the subscapular, which necessarily tend to draw the fragments away from each other, the subscapular being materially aided in this way by the action of the broad dorsal, the great pectoral, and the short head of the flexor of the arm. To accomplish this object, the limb should be put up in two felt, leather, or binder's board splints, the inner of which is nicely padded above to prevent undue pressure upon the axillary vessels and nerves, while the outer is bent well over the top of the shoulder. No cushion will be necessary, especially if the arm and forearm are properly secured to the chest. The elbow is supported in a sling, but not so firmly as to push the head of the bone too high up towards the acromion process. For the first five or six days after the accident, leeches and fomentations may be required. Passive motion should be instituted at the end of four or five weeks.

Fractures of the humerus, especially of the superior part of the bone, are often attended with a remarkable disposition to overlapping of the ends of the fragments from the action of the muscles of the arm and chest, particularly the great pectoral, and great teres, which generally draw the upper fragment inwards and backwards more or less away from the lower broad dorsal. In most cases, however, the tendency rapidly disappears spontaneously, as the irritation of the muscles subsides, so as to permit the fragments to fall into their natural position. The ordinary dressings are generally quite sufficient to keep the parts in apposition, provided the elbow is permitted to hang free and the forearm is well supported, the weight of the arm thus counteracting any tendency to displacement. I have, indeed, never witnessed an instance in which there was any trouble of this kind. If such a contingency, however, should arise, it could readily be remedied by attaching a weight to the lower extremity of the arm by means of adhesive strips, as suggested by Dr. E. A. Clark. The extension apparatus of Dr. Henry A. Martin, consisting of a splint, stretched along the posterior surface of the limb, and regulated by a ratchet operating on two steel bars, might also be worthy of trial.

Epiphyseal Fractures of the Head of the Humerus.—The epiphyseal fracture of the head of this bone is always caused by direct violence, as a blow or fall upon the shoulder, and is peculiar to early life, rarely occurring after the fifteenth year. It has been well described by Sir Astley Cooper, Mr. Robert Smith, Dr. Hamilton, and, above all, by Dr. Moore, of Rochester.

The symptoms, which are generally characteristic, are preternatural mobility of the limb, faint crepitation, even when the ends of the fragments are rudely rubbed together, the retention of the head of the humerus in its normal position, a marked projection below the coracoid process, formed by the upper extremity of the shaft of the bone, and a depression at the distance of about half an inch below the acromion process. The shoulder-joint, viewed in profile, is slightly flattened and increased in breadth. The motions of the arm are more or less impeded.

The diagnosis hinges mainly on the tender age of the patient, the indistinctness of the crepitation, which is much less than in fracture, the preternatural mobility, and the lodgment of the head of the humerus in its normal situation. The upper extremity of the shaft of the bone projects in front of the joint, and, instead of being sharp and angular, as in fractures, is convex, and comparatively smooth. When the parts are displaced, there is shortening of the arm, the elbow hangs off from the side, and the hand cannot, without difficulty, grasp the sound shoulder; all these phenomena being reversed when the fragments remain in apposition. The shortening seldom exceeds half an inch. Any deformity that may exist is readily effaced by extension and pressure, but recurs the moment these efforts are relaxed. The accident is liable to be confounded with dislocation of the shoulder-joint and fracture of the head of the humerus and of the scapula.

The reduction is effected by extension, aided by manipulation, and is maintained by an apparatus similar to that used in fracture of the superior extremity of the humerus. A thick compress should be placed over the inner side of the joint to prevent displacement of the upper extremity of the shaft of the humerus. In neglected cases, the limb eventually, in great degree, regains its normal usefulness, the lower fragment being gradually rounded off, and the capsular ligament elongated.

3. INFERIOR EXTREMITY.

FRACTURES OF THE FOOT.

Fractures of the bones of the foot do not require any special notice, as their management is conducted upon the same principles as that of fractures of the hand. From the fact that they are generally complicated, the treatment must be largely antiphlogistic, and the surgeon will have cause to congratulate himself if he is not occasionally obliged to amputate the foot, or exsect some of its bones. Any loose and displaced fragments, if they cannot be moulded into shape, should always be promptly removed, even when there is no external wound; for such pieces would not only act as foreign bodies, but might, in the event of vicious reunion, seriously interfere with the wearing of a boot. Simple fractures of the toes and metatarsal bones are best managed with the immovable dressing, with the addition of thin binder's-board splints to afford proper support at the seat of injury.

The *calcaneum*, or heel-bone, notwithstanding its exposed situation, the importance of its functions, and the manner in which it lies beneath the tibia and fibula, is seldom the subject of fracture. Direct violence is the most common cause of the accident, which is often attended with severe lesion of the neighboring structures, both soft and hard. Falling from a great height, in which the person alights upon his heel or foot, is the manner in which it commonly happens. The bone being thus forcibly acted upon, on the one hand by the weight of the body, and on the other by the resistance offered by the surface struck, yields at its weakest point, breaking, perhaps, into several pieces. More rarely the accident is produced by the inordinate contraction of the muscles of the calf, as in dancing and leaping; but in this case it is only the posterior extremity of the bone that suffers, its tip being the part generally torn off. The amount of displacement varies according to circumstances, being necessarily very slight when the fracture extends across the body of the bone, whereas it is always very considerable when it involves its back part, on account of the action of the gastrocnemial muscles, which, exerting their influence through the tendo Achillis, sometimes draw up the posterior fragment from an inch and a half to two or even three inches. An impacted fracture of the calcaneum has been met with, but is extremely uncommon.

The symptoms of this fracture are always sufficiently characteristic when the posterior portion of the bone is broken off, the hollow at the heel, the protuberance at the lower and back part of the leg, and the impossibility of flexing the foot, being unmistakable evidences of the nature of the accident. Upon bringing down the upper fragment in contact with the inferior, crepitation may be obtained, although it will be very faint if only the tip of the bone has been detached. The diagnosis will be more difficult when the fracture extends across the body of the calcaneum; for then there will be no displacement, the lateral and interosseous ligaments keeping the posterior fragment in position. In general, however, it may be determined by the history of the case, and by making pressure upon the calcaneum in different directions, thus eliciting crepitation if fracture actually exist.

A fracture of the calcaneum from the laceration of its fibres is usually slow in healing, on account of the difficulty of keeping the fragments in contact, the muscles of the calf constantly tending to separate the upper from the lower. For this reason the union is generally ligamentous, and a long time is necessarily required for the complete restoration of the functions of the foot. When the fracture is caused by direct violence, the repair is effected in the ordinary manner.

When the accident is accompanied by much contusion of the soft parts, antiphlogistics should be freely used before the permanent dressings are applied. The nature of these dressings must depend upon the presence or absence of displacement. In the former case, the chief obstacle to the cure is the contraction of the gastrocnemial muscles, which must, therefore, be effectually controlled until the consolidation is sufficiently advanced to enable the upper fragment to maintain its position independently of extrinsic aid. The least objectionable contrivance for this purpose is a short splint, of perforated zinc, well padded, and adapted to the shape of the limb, the anterior part of which it should cover from the middle of the leg nearly as far as the toes. When zinc cannot be obtained, wood, felt, sole-leather, or binder's board may be used. The object of this splint is to maintain the leg and foot in a permanently flexed position, to relax the muscles of the calf. To maintain the upper fragment in place, the leg and foot may be bandaged in opposite directions, adhesive strips and a compress having previously been applied around

the heel and sole. This position should be observed for at least six weeks, or until the connecting medium is firmly established. When the tendency to displacement is very great, the division of the tendo Achillis may become necessary. The apparatus of Petit, formerly so popular in the treatment of this form of fracture, is worse than useless, as the tendency of the cord and slipper is to separate the upper fragment and to irritate the soft parts about the heel.

In the other variety of fracture, as there is no displacement, all that is necessary is to subdue inflammatory action, and to keep the foot and leg in a quiet and relaxed position with a tin case, or two light side splints, the limb lying upon its outer surface over a pillow, with a proper support for the foot.

Fracture of the *astragalus* is very uncommon, especially the simple variety; the accident is generally complicated with fracture of the tibia and fibula, severe injury of the soft parts, and dislocation of the fragments. The latter lesion existed in eight cases out of ten of fracture of the astragalus collected by Dr. Monahan.

In consequence of the severe injury inflicted in this accident upon the foot and leg, primary amputation will frequently be required. If this be neglected, the patient may perish from erysipelas, mortification, pyemia, or hectic irritation. When the fracture is complicated with dislocation, without serious lesion of the ankle-joint and the soft parts, an attempt should be made, by extension, counterextension, and pressure, aided, if necessary, by the subcutaneous division of the resisting structures, to restore the fragments to their proper position; if this fail, excision must be performed.

FRACTURES OF THE TIBIA.

The tibia, like other long bones, is liable to give way at various points of its extent, but more frequently below its middle than anywhere else. A fracture of its condyles is unusual, and its occurrence is always denotive of great direct violence. Occasionally the bone is broken near its upper extremity, from an inch to an inch and a half below the knee. The internal malleolus is sometimes detached by a twist of the ankle, by a fall upon the sole of the foot, or by direct injury.

The ordinary cause of fracture of this bone is external violence, as a blow or fall. A fracture of the tibia from a fall upon the foot is by no means uncommon. The bone sometimes gives way under muscular action, especially in very old subjects, in whom the osseous tissue is often unusually rarefied and brittle. Complicated and comminuted fractures of the tibia are more frequent than in any other piece of the skeleton.

Fig. 520.

An instance of intrauterine fracture of the tibia, in the sixth month of pregnancy, caused by violent pressure upon the abdomen, has been reported by Dr. Proudfoot, of New York. Madame Lachapelle saw a case of separation of the upper epiphysis of this bone, from traction of the child's foot during parturition; and Dr. Voss met with an example of diastasis of the inferior epiphysis from a fall in a lad fourteen years of age.

Most fractures of the shaft of the tibia are oblique, very few, if any, transverse; nevertheless, as the fibula retains its integrity, there is seldom any considerable displacement, the sound bone acting as a splint to the broken one. It is not often, however, that the fragments completely retain their apposition; in general, there is some degree of separation, which may always be easily detected, even when there is a good deal of tumefaction, by passing the finger along the tibia, and tracing its outline. If there be a fracture, it will manifest itself by an abnormal depression at some particular point, or by an unnatural projection, sufficiently obvious to establish at once the nature of the case. The amount of this projection is occasionally very great, especially when the upper fragment is very long, sharp, and oblique, in which event it is generally extremely prominent, and with difficulty prevented from piercing the skin. The annexed drawing, fig. 520, from a preparation in my collection, conveys a good idea of this form of the injury. For the reason just mentioned, there will usually be very little, if any, crepitation. The fracture, if perfectly free from complication, unites in from four and a half to five weeks.

Oblique Fracture of the Tibia.

A peculiar form of fracture of the tibia, originally described, in 1855, by Gosselin, under the name of the V-shaped, cuneiform, or spiroidal fracture, although infrequent,

is worthy of special notice on account of the gravity of its prognosis. In this country attention was first directed to it by Dr. R. M. Hodges, of Boston. It is often, if not generally, associated with fracture of the fibula, and usually occurs at about the junction of the middle with the lower third of the tibia, the line of fracture representing the form of the letter V, with the base looking upwards, while the apex terminates in a fissure which extends obliquely or spirally down around the shaft of the bone, into or near to the ankle-joint. The mechanism of the injury is not well understood, and there are no signs by which it can be distinguished from an ordinary fracture in this situation. The prognosis is always grave, the lesion, especially if compound, as it generally is, being very liable to give rise to erysipelas, pyemia, and osteomyelitis from exposure of the medullary canal. Fatty emboli, in a putrid state, have been repeatedly found in the lungs of persons dead from the effects of the injury. The only safety of the patient, as experience has clearly shown, in compound V-shaped fractures of the tibia, is in prompt amputation of the limb.

Fracture of the internal malleolus is met with in various forms. In some cases, the process is broken off at, or close to, its connection with the lower end of the tibia; in others, near its articular extremity; but the most common site of the lesion is about the centre of the process. Its direction is nearly always oblique; rarely, if ever, strictly transverse or perpendicular. Occasionally the process is comminuted or broken at several points. Finally, cases not unfrequently occur in which the fracture coexists with fracture of the lower extremity of the fibula. The diagnosis is easily established by the position of the foot, which is always turned upwards and inwards, as if it were partially dislocated, and by the facility with which the detached piece of bone may be moved about with the thumb and finger; a procedure which also readily elicits crepitation.

The most simple contrivance for the *treatment* of fracture of the tibia is a tin case, fig. 521, accurately shaped to the limb, provided with a foot-piece, and reaching a few inches above the knee. A bandage is applied in the usual manner, and any tendency to displacement is easily counteracted by means of a compress and a short splint, arranged so as to bear gently and equably upon the ends of the fragments. I have never found it necessary to employ any other apparatus than this, no matter where the tibia was broken. When the fracture involves the malleolus the foot-piece will effectually prevent displacement. In fracture of the superior extremity of the tibia, extending into the condyles, the plan usually adopted is to place the leg and thigh in the straight position, so as to compel the condyles of the femur to support the broken bone, extension and counterextension being made with two long splints. Such a contrivance, however, will be entirely unnecessary if the tin case be employed, especially if it be sufficiently long to embrace the inferior third of the thigh, as it will thereby completely counteract any tendency in the muscles of the limb to draw the upper fragment backwards into the popliteal space. An efficient appa-

Fig. 521.

Tin Case.

ratus for these fractures will also be found in Dr. Welch's splints, fig. 522; and in the wire splints of Dr. Bauer, fig. 523, the latter being particularly valuable on account of their light, airy, and pliable character.
Fig. 522.

Welch's Splints.

Mr. John Croft is a warm advocate of the treatment of fractures of the leg, whether of one or of both bones, by the use of two plaster of Paris splints, carefully adapted to the

sides of the limb, and applied as soon as possible after the infliction of the injury. He does not hesitate to adopt this method even when there is considerable inflammation of the soft parts, as evinced by discoloration or discoloration and the development of vesicles, provided the circulation is unimpaired. Mr. Croft's position of surgeon to St. Thomas's

Fig. 523.
Bauer's Wire Splits.

Hospital, one of the largest institutions of the kind in the world, justifies him in taking high ground in relation to this mode of management, especially when he can back up his experience by an appeal to 587 cases thus treated without any ill results. Professor Little, of New York, is also an advocate of this method of treatment in a modified form.

The sharp point of bone which occasionally remains after fracture of the shaft of the tibia, in consequence of the inordinate projection of one of the ends of the fragments, generally, in time, disappears through the agency of the absorbent vessels, the parts becoming softened, rounded off, and entirely harmless. When the projection is very considerable, causing pain and ulceration of the skin, and resisting the usual remedies, the best plan is to remove the offending structures with the surgical engine, or the pliers and chisel, as I have done with excellent effect in several instances.

FRACTURES OF THE FIBULA.

Fracture of the fibula is, relatively considered, a sufficiently common occurrence, its frequency being due apparently to the slender form of this bone, to its superficial situation, and, above all, to the important part which it plays in the formation of the ankle-joint. The accident may take place at any portion of the bone, but is by far most common in the inferior fifth of its extent, owing to its intimate connection with the astragalus, which, constituting the pivot of the foot, readily receives and transmits the various shocks to which the latter is so continually exposed. Of fractures of the shaft and head of the fibula no particular description is necessary, since they are always easy of detection, and the treatment does not differ materially from that of similar injuries of the tibia. But it is different with fractures of the inferior fifth of the bone, where, as just stated, the lesion is most common, and where, from being usually associated with other mischief, it is extremely liable to be followed by deformity and permanent lameness. For these reasons, fractures in this situation require to be studied with more than ordinary care.

Fractures of the fibula are much more common on the right side than on the left. In 207 cases collected by Dupuytren, more than two-thirds involved the right leg. The statistics of Malgaigne show that it is most frequently met with between the ages of twenty-five and fifty, and that men are more than four times as liable to it as women. Of 104 cases examined by this author, not one occurred before the fifteenth year.

The causes of fractures of this portion of the fibula can only be properly appreciated by a careful examination of their mechanism. The tibio-tarsal articulation, being a hinge-joint, admits only of flexion and extension, its lateral movements being restrained by the two malleoli, and the ligaments by which the bones of the leg are connected with those of the foot. Hence, the latter cannot be turned outwards or inwards to any considerable extent without producing a fracture of the former, the site of injury being determined by the particular inclination of the limb. Thus, when the foot is forcibly abducted, its inner edge resting on the ground, the upper surface of the calcaneum will be pressed violently

against the external malleolus, in a direction parallel to the fibula, which will, consequently, yield at its weakest point, which is about an inch and a half above the joint, at the part sometimes called the neck of the bone. In most cases there is a rupture of the deltoid ligament, if not also a fracture of the internal malleolus. When the foot is forcibly abducted, the astragalus becomes the immediate cause of fracture, for this bone, turning upon its antero-posterior axis, escapes from the arched cavity formed by the tibia and fibula, and, pressing against the outer malleolus, breaks the fibula nearly at the same level as in the preceding case, the direction of the fissure being usually somewhat oblique. The external lateral ligament is either torn or violently stretched.

The most ordinary cause of this fracture is a fall upon the foot, in which this portion of the limb is forcibly inclined laterally, at the moment the weight of the body impels the bones of the leg forcibly against those of the foot, rendered stationary by the resistance offered by the ground. The fibula may also be broken across by violence applied directly to the part, as a blow, or the passage of the wheel of a carriage. Of 207 cases of this accident, recorded by Dupuytren, 120 were the result of forcible adduction, and 60 of forcible abduction, the rest being caused by direct violence.

However the fracture may be induced, the superior extremity of the inferior fragment is always thrust inwards against the tibia, while the inferior extremity of the superior fragment either remains fixed, or inclines in the same direction. The latter usually happens when the injury is direct, the former when it is indirect.

The inferior extremity of the fibula is sometimes broken almost vertically; such an occurrence, however, must be extremely uncommon, and I have seen only two instances of it, both of them being in the Mütter collection. In one, represented in fig. 524, the bone looks as if it had been split, the fissure extending upwards, almost in a straight line, fully an inch and a half; the posterior, longer, and larger fragment being pushed considerably backwards, so as to form with the other an intermediate triangular space. In the other bone the fracture is also vertical, but the separation is much less.

The *symptoms* of fracture of the lower extremity of the fibula vary according to the circumstances of the case. When this bone alone is severed, the chief signs will be slight eversion of the foot, a depression at the site of injury, and some change, usually not very conspicuous, in the contour of the ankle-joint. When the internal malleolus is broken off, or when the tibia has given way a short distance above the articulation, these characters will exist in a more marked degree, and point out unerringly the nature of the lesion. The foot will be so much abducted as to present the appearance of being dislocated outwardly; the width

Fracture of the Fibula.

between the two malleoli will be much increased; the hollow at the line of fracture will be quite deep; and the external margin of the foot will be considerably elevated, while the internal will be proportionately depressed. Upon taking hold of the foot, it will be found that it is unusually movable, and that it can easily be restored to its natural relations, but that the moment the grasp ceases it will return to its former position. In performing these manipulations, crepitation is very easily perceived; and, upon tracing the outline of the lower portion of the bone, the finger usually sinks in at the seat of fracture, owing to the fact, previously mentioned, that the upper end of the lower fragment always falls over towards the tibia. A good deal of ecchymosis is often present, and a considerable amount of swelling quickly follows, obscuring the characteristic features of the injury, and embarrassing the diagnosis. The only accident with which fracture of the inferior extremity of the fibula is liable to be confounded is a sprain of the ankle-joint, from which, however, it may always readily be distinguished by the great distortion which attends it, and by the presence of crepitation.

A simple fracture of the fibula in the inferior fifth of its extent will, if properly treated, usually unite in a month, without any deformity of the limb, although even then a considerable time will elapse before the ankle-joint will perfectly regain its functions. When the injury is complicated with rupture of the ligaments, fracture of the corresponding portion of the tibia, or other serious lesion, the repair will be much slower, and there will be danger, unless the case be managed with the most consummate skill, of permanent deformity and lameness, the former manifesting itself in an everted condition of the foot and in increased width of the ankle-joint.

The material point in the *treatment* of fracture of the fibula in this situation is to maintain the foot in a position the reverse of that which it assumes in consequence of the

injury. To accomplish this object, which is designed to draw away the upper extremity of the lower fragment from the tibia, and to restore it to its proper relations, the limb, after having been enveloped in the ordinary bandage, with the precaution of not compressing it opposite the site of fracture, is placed in a tin case, the foot being directed permanently inwards. The requisite inclination may easily be imparted by means of a piece of roller, or a few adhesive strips, carried around the instep and heel, and attached to the inside of the leg. Or, instead of this, the fracture may be treated with Dupuy-

Fig. 525.

Dupuytren's Apparatus.

tren's apparatus, fig. 525, consisting of a light wooden splint and a wedge-shaped cushion, the former reaching from the upper third of the leg to about three inches below the sole of the foot, and the latter from the same point to a level with the ankle. The limb being bandaged in the same cautious manner as in the former case, the apparatus is stretched along its inner surface with the tapering end of the pad upwards, and secured, first above, and then below, the roller being passed around the foot and ankle in such a manner as to turn the internal margin of the foot upwards and inwards. The limb may afterwards be kept in the extended position; or, what is preferable, placed, half bent, upon its outer surface, over a large pillow. The parts are diligently watched, the dressing being changed as occasion may require, and passive motion instituted at the end of the third week, and diligently repeated for many months. The ankle-joint always remains weak long after the fracture has become consolidated, from an extension of the inflammation consequent upon the injury.

FRACTURES OF BOTH THE TIBIA AND FIBULA.

Fractures of both bones of the leg are sufficiently common, particularly in young and middle-aged subjects, and are deserving of special attention, on account of the difficulty of their management, and their liability to be followed by deformity and lameness.

Much diversity obtains in regard to the seat of these fractures, as well as their direction, and the nature and extent of their displacement. In twenty-two specimens, contained in the Mütter collection and my own, I find that in ten the tibia and fibula were broken at their inferior extremity, the line of separation in none of them extending beyond three inches above the joint. In four the tibia gave way at its lower third, and the fibula at from two to three inches and a half from its head, or junction with the upper end of the tibia. In six of the cases the tibia was broken from two to three inches above its inferior articulating surface; in two of these the fibula had yielded at its middle, and in the remaining four at different points of its extent. In only two cases had both bones been broken at the same level; in one of these the fracture occurred at the middle of these pieces, and in the other a little below that place.

In the twenty-two cases here referred to, the tibia had been broken only twice above its middle; whereas the fibula had given way above this situation in six cases. In sixteen of the cases the seat of fracture of the tibia was either at the ankle-joint, or below the middle of the bone, generally in its inferior fourth or third. In ten cases of fracture of the fibula the seat of the injury was either at the joint, or within the first three inches from its articulating extremity.

From the above examinations it follows, first, that the tibia and fibula rarely break on the same level; secondly, that both bones are most liable to yield either at the ankle-joint, or within the first three inches above that point; and, thirdly, that the fibula is more frequently fractured at its superior extremity than the tibia.

An examination of these specimens has supplied me with some other interesting facts. Thus, I have found that the fracture in nearly all was more or less oblique, the line of separation in fifteen specimens of broken tibia extending from above downwards, and from without inwards. As a natural consequence of this occurrence, the superior extremity of the inferior fragment projected outwards towards the fibula, which it touched in several of the preparations, on account of a want of proper adjustment during the treatment; the lower extremity of the upper fragment, on the contrary, projected inwards, and had, apparently, generally been much the sharper of the two. The fibula, in most of the specimens, afforded evidence of having been broken across more abruptly

than the tibia, but still with a considerable degree of obliquity in almost every instance that I inspected.

In recent fracture of the tibia, complicated with fracture of the fibula, the inferior extremity of the upper fragment is generally remarkably sharp, and, consequently, often projects through the skin at the time of the injury, the same cause that produces the lesion forcing it across the soft parts. Or, if it is not pushed out at the moment of the accident, it frequently escapes afterwards, through ulceration, induced by the pressure which it exerts upon the overlying structures. The obliquity of fractures of the tibia is often very extraordinary, and there are few instances in which it does not become a source of great suffering to the patient, and of annoyance to the surgeon, on account of the trouble that is experienced in keeping the parts in their proper relations. This is more especially the case when the fracture, situated at the lower fourth of the tibia, is directed from above downwards and forwards, in consequence of the constant tendency of the muscles of the calf to draw the inferior fragment backwards and upwards. When the direction of the fracture is reversed, the extremity of the inferior fragment projects forwards, riding over the lower end of the upper fragment. In either event, the fracture is often rendered compound by the pressure of the sharp extremity of the bone against the soft parts.

A rare form of fracture of these two bones is represented in fig. 526, from a specimen in my collection. The tibia was broken off immediately above its articulating surface with-

Fig. 526.
Fracture of the Tibia and Fibula at the Ankle-joint.

out affecting the internal malleolus, while the fibula had given away about an inch and a quarter above the joint. The foot was characteristically everted. In fig. 527, also from a specimen in my possession, the fracture was comminuted, and extended into the ankle-joint, the articular surface of the tibia having been broken into several pieces, one of which embraced the internal malleolus. The fibula had given way about two inches above its inferior extremity.

The most common causes of this accident are falls, as in slipping upon the ice, or when the foot is suddenly caught in a hollow, or between two hard, resisting objects, so as to throw the whole weight of the body upon the leg. In a case, recently under my observation, both bones gave way just above the ankle by the foot being caught in the fold of the carpet. It may also be caused by a fall from a considerable height, in jumping out of a carriage under full speed, and by direct violence, as the kick of a horse, the caving in of a sand-bank, or the fall of a heavy stone. An instance of fracture of both bones of the leg by muscular action, in a man forty-two years old, has been recorded by Hevlbard D'Arcy.

Fig. 527.

Fracture of both Bones of the Leg at the Ankle-joint.

The *symptoms* of the injury, however induced, are generally well marked, if not positively unmistakable. In nearly every case the limb is shortened from one and a half to three inches, and there is also, generally, great deformity in its diameter, both depending upon the overlapping of the fragments, which, as already stated, is frequently very extraordinary. Besides, upon making extension and counterextension, it is generally easy to elicit crepitation. When the fracture is very oblique, the lower end of the superior fragment may usually be felt immediately beneath the integument, forming a sharp, prominent projection either in front of the limb, or at its inner aspect. Sometimes the soft structures are much bruised and ecchymosed. Another remarkable symptom, one, indeed, which is seldom absent, is a spasmodic twitching of the limb, coming on soon after the accident, and frequently lasting for several days or even weeks, much to the annoyance and distress of the patient.

When the fracture is situated just above the ankle, the foot is usually a good deal everted, causing an appearance of dislocation outwards, as exhibited in fig. 528, and con-

Fig. 528.

Fracture of the lower End of the Tibia and Fibula.

stituting what is usually known as Pott's fracture. In this form of the injury the fibula is broken at a distance of one and a half to two and a half inches above the joint at the same time that the astragalus is dislocated from the tibia, in consequence of the rupture of the internal lateral ligament, either alone or in conjunction with fracture of the inner malleolus. The foot is everted, not by the action of the long peroneal muscle, but by the vulnerating force, which renders that muscle powerless.

The prognosis of fracture of both bones of the leg may be gathered, in part, from what precedes. In the more simple forms of the injury, attended with but little obliquity, a good cure may generally be effected in from four to five weeks. If, however, the obliquity is uncommonly great, it will be extremely difficult, if not impossible, to effect consolidation in a manner altogether unexceptionable, no matter with what skill and attention the treatment may be conducted. More or less deformity will almost be inevitable, either in the length or in the diameter of the limb, owing to the remarkable tendency of the ends of the fragments to overlap each other, which it is often impossible to counteract successfully by any means that can be adopted for the purpose.

Fractures of the tibia and fibula, like those of the bones of the forearm, are occasionally connected by a bridge of callus, or of new osseous matter, which does not, however, as in the latter, so far as can be determined, impair their usefulness. I have several times met with this occurrence when the lesion was confined to one of these bones; and I have noticed that it is not necessary to its production that there should be any approximation of the ends of the opposite fragments, as it may occur when they are perfectly straight, although any considerable displacement no doubt acts as a predisposing cause.

Treatment.—The treatment of fracture of both bones of the leg, attended with shortening of the limb, must be by extension and counterextension, steadily and persistently maintained throughout, otherwise, as just stated, deformity will almost be inevitable. If, on the other hand, the fracture is transverse, or nearly so, such a procedure may of course be dispensed with, the object being attained by confining the leg in a tin case, or fracture-box, care being taken to keep the great toe constantly on a line with the inner border of the patella, the surest evidence that there is no rotation of the ends of the fragments upon each other. Any tendency to forward, backward, or lateral displacement is generally easily counteracted by means of compresses and short splints, aided, if necessary, by the elastic bandage. The limb may then be placed in an easy position upon a slightly inclined plane, made of a bolster or pillow, or it may be suspended by a cord and pulley to the tester of the bed, as may be found most agreeable or convenient.

Fig. 529.
Dr. Neill's Apparatus for Fracture of the Leg.

Counterextension may be made when the fracture is oblique by means of a box provided with a foot-board, and two lateral splints, one extending to the perineum, and the other to the axilla, as I have generally myself preferred; or, with the contrivance of Dr. Neill, consisting of a box, reaching as high as the middle of the thigh, counterextension being made with adhesive strips, passed through holes at the upper part of the apparatus, and tied on the outside, as exhibited in fig. 529.

The use of the gaiter, fig. 530, in the treatment of fractures of the leg and thigh, attended with shortening and deformity, cannot be too pointedly condemned, as it is almost impossible, in any case, however carefully watched, to prevent chafing, and other inconvenience. A similar remark is applicable, only more forcibly, to the handkerchief, fig. 531, at one time so much employed for this purpose. Both appliances should be proscribed, especially as an admirable substitute may always be found in adhesive strips,

secured to the sides of the limb, as in fig. 532, and at the bottom of the foot to a piece of board about four inches in length and three in width. From this board extends

Application of the Gaiter.

Fig. 531.
Application of the Handkerchief.

a cord which plays over the pulley in the stand, fig. 533, or over the apparatus, fig. 534, devised by Dr. Levis, and attached to the foot of the bed. The requisite weight may be obtained by a bag of shot, piece of iron, or the elegant contrivance of Levis, fig. 535.

Perforated one-pound weights
for Extension.

The annexed cut, fig. 536, represents the method of treating oblique fractures of the leg, recommended by Dr. Swinburne. A narrow, delicate splint and foot-piece are fastened by means of adhesive plaster, while counterextension is made from the knee by strips of the same material looped about the limb below the joint. A strong cord is then passed through this loop, and thence on through a hole in the side splint, opposite the lower part of the thigh, in order to afford the requisite degree of tension. If, after the apparatus has been applied, the limb is not sufficiently steady, adhesive strips must be used as represented in the engraving.

Suspension of the leg may sometimes be advantageously practised, both as it respects

the comfort of the patient and the welfare of the fracture. This may be done either according to the method recommended, many years ago, by Professor N. R. Smith, or by

Fig. 536.
Swinburne's Apparatus.

the very simple contrivance of Mr. Salter, of England, depicted in fig. 537, representing the limb surrounded by the apparatus and slung to the tester of the bed. The case in

Fig. 537.
Salter's Apparatus for Suspending the Leg.

which the leg rests is made of light metal; and the whole contrivance is so arranged as to admit of lateral motion, as well as of sliding up and down, simply by the rolling of the pulley-wheels upon the horizontal bar. The attachment of a foot-piece would greatly improve the apparatus, as the limb could then be more effectually steadied.

The apparatus of Dr. N. R. Smith may be used for fractures of any of the long bones of the lower extremity, whether simple, compound, or complicated. It consists, as is seen in

Fig. 538.
N. R. Smith's Suspending Apparatus.

fig. 538, of two pieces, united by a hinge, after the fashion of a double inclined plane, one corresponding with the thigh, and the other with the leg, the latter supporting a shoe, which is attached by a thumb-screw, and is so arranged as to be rotated outwards or inwards, thereby elevating or depressing the toe, as may be deemed most desirable. The two pieces are supplied with side-boards, joined by the bows of iron beneath; and they are so constructed, both at the knee and at the foot, that they may be elongated or shortened at pleasure. Moreover, a short crutch, movable and well padded, is secured to the inner and upper extremity of the thigh portion, in order to prevent injurious pressure upon the perineum. Another piece, also well padded, movable, and composed of iron, is appended to the superior and outer part of the apparatus, and is fastened around the

trunk by a strong band. The thigh and leg rest on slings attached to the side pieces, the latter being confined in the apparatus by its own weight, aided by a bandage, while the former is supported in front by a well-padded, flexible splint. The whole contrivance is suspended to the ceiling, or to the tester of the bed, by a single cord, attached below the knee, near the centre of gravity of the limb and apparatus. The cord ascends with a slight obliquity from the trunk, so as to effect the requisite extension, by making gentle traction on the limb, which is completely grasped by the apparatus, and consequently firmly held by it. In this manner, the member is compelled to obey all the accidental and necessary movements of the body, thus obviating all strain and tension at the seat of fracture.

In Pott's fracture, the plan of treatment which I have usually found most efficacious is to place the limb in the extended position in a tin or wire case provided with a vertical foot-piece. To counteract the tendency to displacement, a short splint should be stretched along the inner surface of the limb, and secured by means of adhesive strips or several turns of a roller. Mr. Pott thought that deformity was due to the action of the muscles of the leg, and hence his invariable practice was to lay the limb upon its outer side, with the knee moderately bent. My opinion is that this is not the fact, but that the weight of the foot is the direct, if not the only, cause of the displacement, especially after the first few days, and that the difficulty is most easily counteracted by keeping the foot well supported during the after-treatment. Any tendency that may exist in the muscles to produce displacement usually subsides within a few days after the accident.

COMPLICATED FRACTURES OF THE LEG.

Fractures of the leg are not unfrequently complicated, whether involving both bones or only one, as in fig. 539. In the latter case, the tibia, much more frequently than the fibula, is the piece that is most liable to suffer. Such accidents are produced in various ways; sometimes by violence applied to the foot, as when a man jumps out of a second-story window, or falls from a scaffolding; but more generally by direct force, as the passage of the wheel of a carriage, a blow from a stone, or the kick of a horse. When pro-

Fig. 539.
Complicated Fracture of the Leg.

duced by these and similar causes, the lesion is usually situated in the inferior portion of the leg, towards the ankle-joint, which is not unfrequently penetrated. Fractures of the leg, occasioned by railway violence, are always of a comminuted character, the bones being extensively crushed, and the soft parts severely lacerated and contused, if not actually pulpified. Hemorrhage, both venous and arterial, often sadly complicates such injuries, and, along with the shock, sometimes proves speedily fatal, the system, perhaps, never fairly reacting after the accident. Now and then, the nutrient artery of the tibia bleeds profusely. Complicated fractures of the leg, of a very bad character, are also frequently produced by machinery in rapid motion, and by gunshot violence. Sometimes, again, especially when there is unusual brittleness of the osseous tissue, the bones are frightfully broken by causes so trivial as to surprise one how they could have induced such a result.

In whatever manner complicated fractures of the leg may happen, the ends of the fragments, particularly those of the tibia, are extremely liable to protrude at the wound; the latter often in such a manner as to render it very difficult to effect replacement, owing to

their being tightly girt by the edge of the opening in the integument, and also to the great length which so frequently distinguishes them. The symptoms of such accidents are always sufficiently characteristic, since there is usually not only great deformity, but likewise, as just stated, exposure of the ends of the broken pieces. Nevertheless, although no difficulty can attend the diagnosis, under such circumstances, so far as the existence of fracture is concerned, the surgeon should always institute a most careful and searching examination, with a view of ascertaining the true condition of the soft structures, the welfare of which is often much more deeply interested than that of the bones themselves. The first object, in every case of the kind, should be to determine what should be done; whether an attempt should be made to save the limb or whether it should be sacrificed. As a general rule, it may be stated that when—if I may use an antithetical and apparently contradictory expression—the complicated fracture is simple, that is, without any serious lesion of the soft parts, an effort should always be made to preserve the limb, especially if the patient is young and robust, and the bone not comminuted, although perhaps broken at several different points. It is true, such cases sometimes terminate unfavorably, both as it respects limb and life; and it should also be borne in mind that the injury sustained both by the soft and osseous tissues may be much greater and more serious than the eye and hand can possibly trace. The dangers, too, from tetanus, pyemia, erysipelas, secondary hemorrhage, and profuse and exhausting suppuration, are not to be overlooked by the surgeon in his laudable endeavors to save a patient from mutilation; nor is he to forget that such lesions, especially when seated near the ankle-joint, are extremely liable to be followed by ankylosis.

When the bones are severely comminuted, the soft parts terribly lacerated, or the ankle-joint extensively opened—in short, when the limb has been frightfully bruised, torn, and crushed—no one would hesitate to use the knife the moment sufficient reaction has taken place to enable the system to withstand the additional shock. The case even then is frequently a bad one, the patient often rapidly sinking from exhaustion, or soon after from the effects of erysipelas or pyemia.

When an attempt is made to preserve the limb, the indications obviously are to arrest hemorrhage, to coaptate the ends of the broken bone, to place the limb in an easy, comfortable, retentive apparatus, and to moderate the resulting inflammation. These intentions are best fulfilled in conformity with the principles laid down under the head of general observations on fractures. When the ends of the fragments protrude, replacement may usually be readily effected by extension and counterextension, except when they are tightly girt by the edges of the wound, when they must be liberated either with a blunt hook, or by enlarging the opening with a bistoury. When the ends are unusually long

Fig. 540.

Fracture-box.

and sharp, and disposed to protrude despite these efforts, the best plan is to retrench them with the saw or pliers, care being taken, however, not to cut off more than is absolutely necessary. Malgaigne in such cases advises the insertion of an iron screw, attached to a strap encircling the limb, into the projecting fragment, in order to place it in proper position, but of the propriety of such a procedure I entertain great doubt, as it must often be followed by erysipelas and other evil effects. The edges of the wound are accurately approximated by suture and collodion, every effort being made to exclude the air. Hemorrhage is checked in the usual manner. When the blood proceeds from the nutrient artery, and is profuse or troublesome, it may be necessary to plug the canal in which the vessel runs temporarily, with a soft piece of wood. Ample provision must be made for drainage, either by counteropening or the use of suitable tubes. Weak carbolic acid lotions and injections must be freely and frequently used, especially during the first five or six days. In short, everything must be done to maintain cleanliness and to prevent the retention of pus and blood.
The best fracture apparatus is the wooden box, fig. 540, so much used in this city, both in private and hospital practice, consisting of four pieces, one corresponding with the back of the leg, and two with its sides, the fourth being intended for the foot. The latter, projecting nearly perpendicularly, is provided with two mortise holes, for the reception of the extending bands. The two lateral pieces are secured each by two hinges to the back board, so as to admit of being opened or shut at pleasure during the application and removal of the dressings. The limb, enveloped in the bandage of Scultetus, is care-

fully laid into the box, which is then closed, and filled with coarse bran until the whole leg and the spaces on each side of it are completely covered in. The advantage of the bran, thus used, is that it affords not only easy, equable, and comfortable support to the broken bones, but readily absorbs the discharges, and prevents the deposit of the ova of the fly, so common during the hot months of this and other countries. Substitution is effected whenever the bran becomes soiled and caked. This mode of treating compound fractures of the leg, originally suggested by the late Dr. John Rhea Barton, is unquestionably one of the most valuable improvements that have been introduced into the management of this class of injuries, whether it be viewed with reference to the comfort of the patient, the safety of the limb, or the convenience of the surgeon.

The necessary extension and counterextension are easily effected by adhesive strips. For the first week or ten days, leeches and cold water-dressing will generally be required. If suppuration arise, the most soothing application will be an emollient poultice.

The fracture-box need seldom be employed longer than eight or ten days, unless the case is an unusually bad one. By the end of this time it may generally be advantageously replaced by a McIntyre's screw splint, Fig. 541, well padded and extended, suspended in a Salter apparatus, or supported with the plaster bandage, a suitable opening being left opposite the seat of the fracture for drainage and ready dressing. In due time, the patient should be put on crutches, and sent into the open air.

Fig. 541.

Compound Fracture of the Leg, Dressed.

Complicated fractures of the leg are necessarily troublesome and tedious occurrences, requiring the utmost care and attention to prevent deformity and permanent lameness, and even then this is by no means always possible. Erysipelas, in its worst forms, often speedily follows, generally within the first forty-eight hours; copious suppuration arises, the matter, unless evacuated by timely incisions, perhaps burrowing extensively among the surrounding structures; and the system becomes rapidly undermined by hectic irritation, loss of sleep, and impaired nutrition. Great swelling, the result of a deposition of serum and lymph, frequently exists; the limb, tender and heavy, readily pits on pressure; and the joints are stiff, painful, and in danger of permanent ankylosis. The heel, unless carefully watched and protected, is sure to suffer; first, from inflammation, and afterwards, at no distant period, from ulceration, or even gangrene. Most of these local troubles may generally be prevented by the judicious use of the bandage, applied gently and equably, yet somewhat firmly, to support the capillary vessels, control muscular action, and promote the absorption of effused fluids. Passive motion should be instituted by the end of the third week, and daily repeated for many months.

Fig. 542.

Gillingham's apparatus for Ununited Fracture of the Leg.

There are no fractures in the whole body so liable to be attended with tardy union as those of the leg, or which are so frequently followed by deformity. The chief cause of these mishaps is the great difficulty which the surgeon encounters in effecting maintenance of the ends of the fragments, in consequence of their remarkable obliquity and splintered character, especially of the upper one of the tibia, which is often very thin and several inches long.

Ununited fractures of the leg are not uncommon, and may involve both bones, or be limited to one of them. In either event, the treatment is generally tedious and perplexing. In most of the cases under my observation, my main reliance has been upon the use of the perforator and the ivory peg, which have generally rendered me good service. Setons, the steel pin, and excision are inapplicable. When the patient's health is much dilapidated, and exercise in the open air is imperatively demanded, great benefit will accrue from wear-

ing the apparatus, fig. 542, devised by Mr. Gillingham, of England, and which is thus described by Mr. Holmes: "It consists of, first, a collar, which is moulded to the leg just below the knee, and on each side of which is a stud; secondly, of a boot with a socket at the heel; and, thirdly, of two steels, with ankle-joints bifid at the top to catch the studs on the collar, and capable of elongation or shortening, as seen in the engraving. Thus the weight of the body is taken off the leg-bones, and transmitted down the two side-steels." The apparatus can be equally adapted to ununited fractures of the femur.

FRACTURES OF THE PATELLA.

Fracture of the patella, figs. 543 and 544, although comparatively uncommon, derives great practical importance, from its proximity to the knee-joint, and the imperfect manner

Fig. 543.

Transverse Fracture of the Patella.

Fig. 544.
Oblique Fracture of the Patella.

in which it is usually repaired. It may extend through the bone in any direction, transversely, obliquely, or vertically, the frequency of the occurrence being in the order here stated. When the fracture is comminuted, the fissures often exhibit the most irregular arangement. Compound fracture of the patella is an uncommon, but dangerous complication.

The causes of the accident, are two, external violence, and muscular action. The transverse fracture is nearly always produced by the latter, or by the joint agency of the two, while the oblique and vertical are invariably the result of direct injury, as a fall, blow, or kick. In the latter case, consequently, there is frequently severe contusion of the soft parts, and sometimes the knee-joint is even laid open. The transverse fracture is produced by falls in which the leg is

Fig. 545.

Fracture of the Patella.

strongly flexed upon the thigh, while the body is thrown suddenly and forcibly backwards, thereby putting the extensor muscles powerfully upon the stretch, the line of fracture usually taking place just above the middle of the bone. Jumping out of a carriage and falling backwards upon the ground, is a very common way in which the accident is occasioned. Circus riders and ballet dancers sometimes break this bone in the act of leaping in the exercise of their profession.

Desault met with a case in which a man broke both of these bones simultaneously by a violent effort of the muscles to disengage the limbs from the constrained position in which they were placed during the operation of lithotomy.

Muscular fractures of this bone are very uncommon before the age of twenty-five. The greatest number occur between this period and the fifty-fifth year.

Transverse fracture of the patella is sometimes caused by direct violence, as when the bone is struck in a fall or blow, and forcibly impelled against the condyles of the femur. On the other hand, cases occur, although rarely, in which the bone is broken from within outwards, as in fracture of the articular extremity of the femur, in which one of the fragments is violently thrust against the posterior surface of the patella, perhaps shivering it into a number of pieces.

The *symptoms* of fracture of the patella are generally well marked. In the transverse form of the lesion, the nature of the accident is at once detectable by the change in the contour of the knee, by the inability to extend the limb, and by the displacement of the upper fragment, as seen in fig. 545. In many cases the person is conscious, at the moment of the injury, of something having given way, and, perhaps, he may even have heard the peculiar characteristic snap. If he attempts to get up and walk, he will be almost sure to fall, from his inability to extend the leg and support the weight of the body upon it. The displacement is usually considerable, the superior fragment being drawn upwards upon the forepart of the thigh by the extensor muscles. The height to which it may be carried varies according to the extent of the destruction of the ligamentous connection of the tendon of these muscles. When the separation is complete, it may amount to two and a half,

three, and even four inches, while, under opposite circumstances, it may not exceed six, eight, or ten lines, or be even entirely absent, the structures in front of the joint holding the fragments more or less firmly together. The distance between the two fragments is always, as a rule, considerably increased by bending the leg. The front of the knee has a flattened appearance, and upon passing the finger over it its point will be found to sink down abruptly, as it were, into the joint. The lower fragment is stationary, but the upper is easily moved, and may, by thorough extension of the limb, be brought down into its normal situation, so as to enable one to detect crepitation. If some time have elapsed since the occurrence of the accident, considerable swelling may be present, due to an effusion of synovial fluid, or this fluid and to extraärticular deposits, and more or less obscuring the diagnosis; occasionally a considerable quantity of blood is poured into the joint, especially when the fracture has been caused by external violence. The synovial burses over the patella and over the head of the tibia occasionally become greatly inflamed, and thus seriously complicate the case.

In respect to its mode of *union*, the transverse fracture of the patella holds the same relation as a similar injury of the olecranon. In both cases the nutrition of the fragments is seriously impaired by the laceration of their vessels; in both there is an inordinate quantity of synovial fluid, and in both great difficulty is experienced in maintaining coaptation. Hence, as a rule, the union is by fibrous, ligamentous, or fibro-ligamentous tissue, not by osseous. In all the examples of this fracture that I have been able to examine, both in the living subject and in museums, I have not met with any in which the consolidation was completely osseous. A few such cases, however, have been recorded by surgeons, and one well-marked specimen of the kind, found in the dissecting-room of the College, is contained in my private collection. In the inferior animals osseous union is not uncommon, if care be taken to keep the ends of the bone accurately in contact. When the interval between the broken pieces is very considerable, as, for instance, when it amounts to two inches, the union is established by the aponeurotic tissue which naturally covers the patella, and which, in this event, extends from one fragment to the other, the plastic matter which is poured out in consequence of the injury not being capable of being converted into ligamentous matter. Whatever may be the nature of the connecting medium, it is important that it should be as close and perfect as possible; for the joint will always be weak and unprotected precisely in proportion to its length and thinness.

Fig. 546.　　　　　　　　　　　　　Fig. 547.

Arterial Supply of the Patella.　　　Old Fracture of the Patella, showing the Separation of the Fragments.

It is highly probable that the very means that are generally employed to keep the ends of the fragments in contact often serve to interfere with their reunion by cutting off the supply of blood. Mr. Manning has shown by the dissection of a number of specimens that

the vascular arch of the upper fragment is situated at the precise spot where the greatest amount of pressure is usually made by the retentive apparatus; and that the lower fragment inevitably experiences a similar fate when, as not unfrequently happens, the internal, superior, and inferior articular arteries arise from a common trunk. Fig. 546 illustrates Mr. Manning's ideas.

The annexed cut, fig. 547, represents a specimen of fracture of the patella in the cabinet of the late Professor Pancoast. The bone was broken into three pieces, the superior of which was drawn up in front of the thigh, far away from the joint, and nearly four inches from the inferior, which consisted of a mere little chip, hardly two inches in width, corresponding with the lower edge of the bone. No union followed.

The fragments after this accident occasionally experience important changes in form and bulk. Now and then they undergo remarkable atrophy, but more commonly they increase in size and strength, so as to afford a broader surface for the fibro-ligamentous tissue which serves to hold them together.

The *treatment* of transverse fracture of this bone is attended with serious difficulty, on account, first, of the pressure from the accumulation of synovial fluid, and, secondly, of the difficulty experienced in controlling the action of the extensor muscles, the constant tendency of which, especially during the first six or eight days, is to draw the superior fragment upwards, away from the lower. To counteract this tendency, therefore, constitutes the chief indication of the treatment. This can be effected only by maintaining the leg steadily and faithfully in a complete state of extension, the thigh being at the same time flexed upon the pelvis, and the body kept in the semierect posture. In this manner, the extensor muscles are thoroughly and effectually relaxed. The most efficient contrivance for insuring this position of the limb is a strong, well-padded tin or wire case, long enough to reach from the middle of the thigh to the corresponding point of the leg, a roller having previously been applied from the toes upwards, and another from the groin downwards. The superior fragment, having been brought into place, is next confined by numerous adhesive strips, carried around the bone above and below the joint, and connected afterwards by vertical and transverse pieces. The dressing is completed by the application of a long, thick, and rather narrow compress, extended around the upper border of the patella, and confined by the two rollers passed around the joint in the form of the figure 8. Managed in this way, it is hardly possible for the fracture to suffer the slightest displacement, or to conceive of anything better adapted to fulfil the end in view. The tin or wire case maintains the limb in the extended position, the adhesive strips and compress retain the upper fragment in contact with the lower, and the rollers, applied in opposite directions, aid powerfully in controlling muscular action. Leeches, ice, and lotions of acetate of lead may be required when the parts are much contused or otherwise injured, and no good can result from any attempt to approximate the fragments so long as the joint is distended with synovial gland. Hence the best plan, during the first six or eight days, is to limit the treatment to the employment of rest and other antiphlogistic means, all corrective appliances being dispensed with until the immediate effects of the injury have passed off. When the quantity of effused fluid is unusually great the aspirator should be used, and the same plan may be adopted when the joint is filled, as is occasionally the case, with uncoagulated blood.

Fig. 548.
Hamilton's Apparatus.

When a suitable case cannot be procured, the object may be attained by the use of a wooden splint, well padded, and stretched along the posterior part of the thigh and leg. The adjoining drawing, fig. 548, represents the mode of dressing transverse fractures of the patella, pursued by Professor Hamilton, and also, at one time, with slight modifica-

tions, at the Pennsylvania Hospital. The plan is an excellent one, and seldom fails to effect a good cure; often with hardly any interspace between the ends of the fragments.

Mr. Erichsen, as a rule, prefers the immovable dressing, with which he has generally effected excellent cures. He applies a pad above the upper fragment and secures it with a figure-of-8 bandage, as a preliminary step. Manning's apparatus, fig. 549, which has met with much favor in England, "consists," observes Erichsen, "of a wooden back-

Fig. 549.
Manning's Splint for Fractured Patella.

piece, a little wider than the knee-joint, and long enough to reach from the sole of the foot to the gluteal fold, and provided at the lower end with a foot-piece, A. At the junction of the middle and lower thirds is a transverse oblique slit, B, one and a half inches long. Strips of strong plaster, two inches broad and long enough to encircle the thigh and overlap by some inches, are attached to a calico band, C. The free end of this band is carried through the slit, and the straps of plaster are open on the upper part of the splint. A piece of wood, E, is attached to the lower part of the splint, and another piece of corresponding size is attached to a loop at the end of the calico band, so that, when drawn down and the splint is adjusted, these three pieces may be five or six inches apart."

The limb having been previously bandaged from the toes up as far as the lower edge of the patella, and the splint well padded without obstructing the slit, an assistant draws down the upper fragment by grasping the extensor muscles, while the surgeon carries the plasters firmly around the thigh from above downwards, beginning immediately below the gluteal fold, and terminating about three inches from the upper border of the patella. The calico band being kept carefully in the middle line is then fastened to the splint by a few turns of a roller. "Lastly," says Erichsen, "as many elastic rings—those known as 'office bands' answer the purpose very well—as will serve to approximate the fragments without causing too much pain to the patient, are passed over the projecting ends of the pieces of wood, as at F, fig. 550, on each side of the splint, so as to exercise sufficient traction on the muscles pulling on the upper fragment."

Fig. 550.
Manning's Splint applied.

Numerous contrivances are before the profession for the treatment of these injuries, nearly all constructed upon the same principles. Among the more ingenious are those of Lonsdale, Burge, Lausdale, and Boisnot. The iron ring, employed by Albucasis, De Vigo, Bassuel, Purmann, Heister, and others in the treatment of transverse fractures of the patella, was reintroduced into practice, in 1866, by Dr. W. A. Gibson, of Missouri, and in the case reported by him bony union is said to have taken place in thirty days, followed by the perfect use of the knee-joint. The ring, being well padded, is secured first to the knee by adhesive strips, and then by a roller to a light splint, two feet in length,

stretched along the posterior surface of the thigh and leg. Perhaps the very best of these contrivances is that of Wolfermann, consisting of a simple, padded steel spring, encircling the knee from behind, and ending in front in two cresecentic arms, so arranged as to embrace very closely the periphery of the patella, and kept in place by two leather straps. The apparatus, properly applied, effectually prevents flexion of the joint, and induces accurate apposition of the fragments. A splint should be stretched along the posterior surface of the limb in every case in which such a contrivance is used. Excellent results have followed this mode of treatment in the hands of Eve, Blackman, Kocher, and others.

The hooks of Malgaigne, delineated in fig. 551, were employed by that eminent surgeon in a considerable number of cases, with bony union in some, and no bad results in any; and they are now used a good deal both in this country and in Europe. The shape and construction of the instrument are perceived at a glance. Two of the hooks are inserted into the tendon of the extensor muscle, at the upper edge of the patella, and two into the lower, when they are drawn together, and kept in place by the screw. The hooks cannot penetrate the bone, much less the joint; and the only objection to them is that they may produce erysipelas. The great advantage is that they prevent the ends of the fragments from tilting up in front, thus holding them more closely and firmly together, and thereby more effectually insuring osseous union. From six to eight weeks is the period during which they should be retained.

Fig. 551.

Malgaigne's Hooks.

This treatment in this form of fracture has of late years been very fashionable at the Pennsylvania Hospital in the hands of Drs. Levis and Morton, who prefer it to every other method. Professor Agnew, on the contrary, denounces it as " diabolical." My own opinion is that it is perfectly safe when skilfully employed and carefully watched. The instrument used by Levis is composed of two separate hooks, fig. 552, an arrangement which has the advantage, as is claimed, of holding the fragments more evenly and firmly together than can be done with the original contrivance. Morton has still further modified the instrument by imparting to it, as seen in fig. 553, the form of a double triangle. That this treatment has been occasionally followed by ulceration of the joint and even the death of the patient is unquestionable, and hence it cannot be employed with too much caution. As a rule, however, I believe it to be perfectly safe.

Dr. John Rhea Barton, upwards of half a century ago, in one instance, connected the fragments together with silver wire, but lost his patient. The operation was not repeated until 1861, when it was successfully performed by the late Professor E. S. Cooper, of San Francisco, and, three years later, by Logan, of Sacramento. Dr. Hector Cameron, of Glasgow, in 1877, successfully wired the fragments under antiseptic precautions, and similar operations have now been performed in 17 additional cases, Lister having had three, and Rose and Schede each two, while single cases have been recorded by Van der Meulen, Smith, Metzler, Socin, Langenbuch, Trendelenburg, Uhdé, Bell, Holmes, and Schneider. All of the 18 cases recovered with useful limbs, except three in which the joint suppurated and became ankylosed. The operation unfortunately has not been performed sufficiently often to justify us in offering any positive opinion respecting its safety. Lister declares that it should never be employed except by practitioners who are thoroughly conversant with antiseptic surgery. I certainly should doubt the propriety of resorting to it under any other circumstances, and even then it must always be a dangerous procedure.

Volkmann connects the fragments by passing a silver wire or a strong silk ligature subcutaneously through the tendon of the extensor muscles and the ligament of the patella, and he has reported a number of cases in which he succeeded in obtaining, by this procedure, excellent osseous union. It is evidently too soon to praise or condemn this operation; but its dangers are certainly less than those attendant upon the operation which opens the knee-joint.

The injection of fresh marrow cells between the fragments, as practised by Ollier, Goujon, Wyeth, and others, has failed to secure the desired object, and scarcely deserves repetition.

Instead of raising the heel in the treatment of transverse fractures of the patella, some surgeons place the limb in the horizontal position upon a well-padded posterior splint, provided with a footboard, and extending nearly as high up as the tuberosity of the ischium, the patient observing the semierect posture as he lies in bed. The extensor muscles, it

is alleged, if not paralyzed by the accident, soon become so completely relaxed as not to exert any strain whatever upon the fragments. After the immediate effects of the injury have subsided the parts are approximated with adhesive strips, and supported with compresses and the immovable bandage. Excellent cures may no doubt be obtained by this method, but I give the elevated position a decided preference. Dupuytren declares that he treated some cases of transverse fractures of the patella successfully without the employment of any apparatus whatever, simply by keeping the limb perfectly at rest in the extended position.

Fig. 552.   Fig. 553.
Levis's Hooks applied.   Morton's Hooks applied.

Oblique and vertical fractures of the patella generally readily unite by osseous matter, as there is but slight tendency to displacement of the fragments, owing to the fact that they are little, if at all, influenced by the action of the extensor muscles of the thigh. The prognosis is, therefore, other things being equal, always favorable, although, from the involvement of the knee-joint, a considerable period usually elapses before the patient regains the perfect use of the limb.

The signs of these oblique and vertical fractures are sometimes very obscure, especially when there is much swelling of the soft parts. In general, however, the nature of the case may be determined by the impaired motion of the knee-joint, by the fixed character of the pain, and by pressure applied to the patella in opposite directions, when, if such lesions exist, crepitation will be sure to be elicited.

The limb, having been enveloped in a bandage, should be kept at rest in an elevated and extended position until there is complete subsidence of inflammation, when the water-glass dressing should be applied, the patient being permitted to move about upon crutches. If the fracture be vertical, or nearly so, it will be necessary to support the fragments by means of two compresses, stretched along the lateral borders of the bone, and confined by adhesive strips and a roller. When the fissure is very oblique, the displacement may be such as to demand a course of treatment similar to that necessary in transverse fracture.

The stiffness of the knee-joint, which always remains after fractures of the patella, and which is often very great, no matter what mode of treatment is adopted, requires special attention, not for days or weeks, but generally for months, otherwise irremediable lameness will almost be sure to follow. Passive motion should not, as a rule, in transverse fractures, be instituted before the close of the seventh or eighth week, or until there is reason to believe that the process of reunion is sufficiently advanced to withstand the efforts. The adhesions must be broken up gradually and in the gentlest possible manner, and should be repeated, at first, every second day, and afterwards daily, until all danger of ankylosis is over. Friction with stimulating liniments, massage, and the hot and cold douches will do much in stimulating the absorbent vessels, and restoring the parts to their primitive suppleness.

A patella that has once been broken transversely is exceedingly liable to a recurrence of the accident from comparatively slight muscular contraction. The patient should, therefore, always be put upon his guard in this respect. The fracture may occur at the

same point, but generally it takes place a little higher up. Finally, when one patella has been broken, the other is apt to suffer in a similar manner, owing to the imperfect use of the affected limb, and the consequent liability of the patient to fall. Cases of this kind have occurred in my own practice, and others are referred to by Bromfield, Meuschner, Camper, Sir Astley Cooper, Malgaigne, and other high authorities.

In all fractures of this bone it is a good rule, after the first ten or twelve weeks, to protect the knee for a long time with a suitable gum-elastic cap, to rub the parts well at least once a day with some stimulating liniment, and to observe the greatest possible care in the use of the limb. The extensor muscles, especially the straight, always remain very weak after transverse fractures of the patella, and in many cases they experience a remarkable degree of atrophy, which generally lasts through the remainder of life.

Compound fractures of the patella, with penetration of the synovial membrane, are among the most dangerous of accidents, life, when an attempt is made to retain the limb, being liable to be assailed by profuse suppuration of the knee-joint, erysipelas, pyemia, pleuro-pneumonia, tetanus, and hectic irritation. For these reasons primary amputation is generally demanded. When the bone is comminuted, but the joint is not laid open, all loose fragments should at once be removed, and the case managed upon ordinary principles. In a case of this kind recently under my care, in a youth twenty years of age, owing to previous mismanagement, violent inflammation took place attended with the formation of large abscesses, and followed by necrosis, necessitating the removal of nearly the entire patella. The patient was laid up for upwards of a year, but finally made a good recovery with partial ankylosis of the knee. The great points in the treatment of such injuries are, first, to maintain the limb in an elevated position upon a posterior splint, and to keep the knee constantly covered with a bladder partially filled with pounded ice. If the symptoms are very urgent, and the patient is young and plethoric, blood should be taken freely from the arm and by leeches from the affected parts. The danger to limb and life in such accidents is generally in proportion to the amount of injury sustained by the knee-joint. Incised wounds usually do much better than lacerated and contused. Antiseptic measures should be rigidly enforced. How far they should be trusted in bad cases is an open question.

Secondary amputation may become necessary, when, an attempt having been made to save the limb, life is threatened with exhaustion by profuse suppuration and hectic irritation. Mr. Poland, who has made a special study of compound fractures of the patella, involving the knee-joint, finds, by an appeal to statistics, that such an operation, whether primary or secondary, is much less frequently called for than has generally been imagined. Of 68 cases treated without this extreme measure, only 12, or 17.65 per cent., died, while of 14 cases treated by amputation and excision, 8 perished, thus exhibiting a very great difference in favor of non-interference. In all the fatal cases, as well as in a majority of those that recovered, suppuration of the joint had occurred. Ankylosis, partial or complete, must, of course, in such an event, be a frequent sequence.

FRACTURES OF THE FEMUR.

Fractures of the femur deserve the most attentive study; for not only are they of frequent occurrence, but they present themselves under every possible variety of form, and there are no injuries of the kind which, to use the language of Pott, "so often lame the patient and disgrace the surgeon." Any portion of the bone may give way, and hence it is customary, in treating of the subject, to speak of fractures of the shaft of the femur, of its condyles, and of its superior extremity, or of its neck, and of its trochanters.

1. FRACTURES OF THE SHAFT.

The shaft of the femur may be broken in any portion of its extent, but there are three points which are particularly obnoxious to fracture. These are the upper fourth of the bone, the middle, and the inferior fourth, the relative frequency of the accident being in the order here stated, although it is generally asserted that the bone yields more frequently at or near its middle than anywhere else. This idea, however, accords neither with the results of my observations upon the living subject, nor with my examinations of specimens of fractured bones in different collections. The relative difference, however, is, no doubt, very slight. Fractures of the shaft of this bone are nearly always, in adults and elderly subjects, oblique, and, therefore, liable to be attended with great displacement, the long and sharp ends of the fragments often inflicting serious injury upon the soft parts. In

children, on the contrary, they are more frequently transverse; or, at all events, the obliquity is usually much less, and, as the muscles are less vigorous, the tendency to overlapping is not nearly so marked.

An impacted fracture of the shaft of the femur is sometimes met with, although the occurrence is very uncommon. At a meeting of the Surgical Club, of Philadelphia, in 1878, Professor Agnew exhibited the femur of a gentleman, thirty-five years of age, which had given way about its middle in the act of pulling on his boots, and in which the upper extremity of the lower fragment was partly driven into the upper a distance of upwards of two inches. Death occurred at the end of a fortnight from the effects of erysipelatous inflammation, notwithstanding which there was already a considerable amount of fibrous union.

Fractures of the Upper Fourth of the Shaft.—The most common site of fracture of this portion of the bone is from two and a half to three and a half inches below the small trochanter; the line of fracture is almost always oblique, extending from behind forwards, and from above downwards, being frequently from an inch and a half to two inches in length. A transverse fracture here is an exceedingly rare occurrence. It is also very uncommon to see the bone give way just below the small trochanter, and it is worthy of note that, when it does break at this point, it is generally complicated in its character, or associated with intracapsular fracture, properly so termed.

The symptoms of fracture seated in this portion of the femur are generally so obvious as to indicate at once the nature of the injury, the characteristic signs consisting of great shortening and angular deformity. The shortening varies from two to four inches, and usually exists in full force immediately after the receipt of the injury. The superior portion of the limb is remarkably distorted, being convex on its external surface, with a corresponding concavity internally, occasioned by the overlapping of the ends of the broken bone, the upper nearly always lying in front of the lower, being drawn in this direction by the action of the psoas and iliac muscles, and both being usually drawn somewhat outwards. In ten specimens of fracture of the upper fourth of the shaft of the femur, that I have carefully examined, I find that in all, except one, the upper fragment is in front of the lower, the reverse being the case in the other. In these ten specimens the superior piece is drawn forwards and outwards in six; in two it is tilted upwards and inwards; and in two it is raised up and in a straight line with the lower, or without any lateral deviation whatever. The distance of the fracture from the small trochanter ranges from two inches and two-thirds to three inches and a quarter.

In the six specimens in which the superior fragment is directed forwards and outwards, the lower fragment is also inclined outwards in four, the junction between them being such as to give the bone more or less of an arched appearance, the convexity being external and the concavity internal. In the two specimens in which the upper end is directed forwards and inwards, the lower end, in one, is inclined inwards also, and in the other it is straight, or in a line with the superior fragment. In seven of the eight specimens in which the displacement is lateral, the inferior fragment is more or less strongly everted, and, consequently, the knee and foot, during life, must have been in the same position.

The fractures, so far as can be determined, were all oblique, the line of disjunction, in nine, extending from behind forwards, and from above downwards, one only being in the opposite direction, and in this the lower fragment lies in front of the upper, overlapping it four inches. The distance at which the ends of the bones are separated anteriorly varies from half an inch to an inch and three-quarters. The angle which the superior fragment forms with the inferior does not, in any of the ten specimens, exceed 45°, while in most it falls considerably short of this.

I have been thus particular in giving the results of these examinations, on account of their practical bearing upon fractures of the superior extremity of the shaft of this bone. Sir Astley Cooper, and those who have adopted his views, have evidently formed very erroneous ideas, not only as regards the extent and direction of the displacement of the upper fragment, but also of its causes. Thus, it has been asserted that the upper end often overlaps the other almost at a right angle, which is not the case in any of the specimens that I have examined; on the other hand, it has been alleged that the two pieces are usually inclined outwards, which the specimens alluded to also disprove, there being no lateral deviation whatever in two, while in two others the projection was inward, leaving thus only six cases of outward displacement. The displacement forwards of the upper end is due to the joint action of the psoas and iliac muscles, assisted, perhaps, by the pectineal and the short head of the adductor, while it is dragged outwards mainly by the agency of the external rotators. The lower fragment, on the contrary, is drawn up by the action of the flexor muscles of the thigh, and outwards by the tensor, vastus, and glu-

teal muscles. That the direction of the fracture materially influences the direction of the displacement is shown by the fact that, in the only specimen out of the ten examined by me in which the line of fracture extended from before backwards, and from below upwards, the lower fragment overlapped the upper, and that to a great extent.

Although the specimens here described are, I conceive, of great pathological and practical value, it must not be forgotten that any inferences deducible from their examination are impaired, in some degree, by the fact that the displacement which characterizes them may have been influenced more or less by the nature of the treatment. Thus, in consequence of the use of splints, the ends of the fragments, originally inclined inwards or outwards, may have been pushed and held in the opposite direction, thereby completely reversing the primitive order of the deformity, as caused by the direction of the fracture, the weight of the limb, and the action of the muscles.

The annexed drawings, figs. 554, 555, and 556, two of which are from my own preparations, will serve to illustrate the nature of the displacement so often met with in fractures of the superior portion of the shaft of the femur.

Fractures at the Middle of the Shaft.—A fracture at the centre of the shaft of the femur is, according to my observation, an uncommon occurrence; most generally the bone gives way some distance above or below this point. The line of fracture is, for the most part, very oblique, extending from behind forwards and from above downwards, and the consequence is that the superior fragment nearly always overlaps the inferior, the upper extremity of which is drawn backwards, and usually, also, somewhat outwards, by the action of the flexor muscles, causing thus an amount of shortening from two and a half to three and even four inches, with more or less angularity at the site of injury, and marked eversion of the limb. The lower end of the superior fragment, on the contrary, forms a prominent projection on the forepart of the thigh, easily perceived by sight and touch. The symptoms are characteristic.

| Fig. 554. | Fig. 555. | Fig. 556. |

Fracture of the Shaft of the Femur.

A perfectly transverse fracture of the shaft of the femur is, as stated above, so extremely uncommon that, although the phenomena might be such as to lead to the suspicion of its existence, the idea that it really is an injury of that kind should not be carried out in practice, lest, the requisite extension and counterextension being omitted, permanent shortening should follow. When there is no marked tendency to displacement,

it will generally be found that the fracture, instead of being transverse, is slightly impacted, or that its extremities, being denticulated, are interlocked with each other, and thus held in place. Comminuted fracture of this portion of the shaft is not uncommon, especially in old subjects, laboring under fragility of the osseous tissue.

The accident may be the result of direct violence, as a kick from a horse or the passage of the wheel of a carriage; or it may be occasioned indirectly by a fall upon the foot or knee. In the former case it is often of a compound or complicated character. Several examples have come under my observation in which a fracture in this situation occurred in the act of pulling off the boot, the limb at the moment lying across its fellow.

Fractures of the Inferior Fourth of the Shaft.—Fracture of the inferior portion of the shaft of this bone derives a special interest from the fact that, when occurring very low down, the inferior end of the upper fragment may, particularly if very long and sharp, penetrate the joint, and thus seriously complicate a case otherwise easy of management. The fracture, moreover, is liable to be compound, the upper piece piercing the muscles and integument just above the knee. As in fracture of the other divisions of the shaft, already described, so in this the line of the solution of continuity generally ranges from behind forwards and from above downwards, a transverse fracture, properly so termed, being extremely uncommon. The degree of obliquity, although very variable, is generally so considerable as to cause great shortening of the limb and angularity of the part; which, together with the everted state of the knee and foot, are characteristic signs of the nature of the accident. The inferior fragment is always drawn backwards and upwards, its superior extremity forming a distinct prominence in the popliteal region, which may easily be effaced by restoring the pieces to their proper position. When the fracture occupies the lower extremity of the shaft, nearly on a level with the joint, the upper fragment may descend so far down as to push the patella away from the trochlea of the femur, over upon the tibia, so as to create an appearance simulative of partial luxation of this little bone. If several hours have elapsed since the receipt of the injury, the diagnosis will sometimes be obscured by tumefaction of the joint; but, in general, whatever may be the condition of the parts, any existing doubt may be cleared up by a thorough examination of the

Fig. 557.

Fracture of the Femur at its Inferior Fourth.

limb. The relative positions of the fragments in this fracture are well depicted in fig. 557, from a specimen in my cabinet.

Much swelling in and around the knee often, if not generally, attends fractures in this situation, the former being due to an effusion of synovial fluid from an extension of the irritation to the synovial membrane, and the latter to the extravasation of blood, which is frequently poured out very freely by the lacerated tissues at the seat of the injury, whence it gravitates to the capsule of the joint, but does not penetrate it. An intracapsular swelling is always readily distinguishable from an extracapsular by the fact that, in the former, the patella may be movable from side to side, and rebounds when tapped; whereas, in the latter, it remains firmly fixed.

The causes of fracture in this situation are commonly of a direct nature, a greater amount of force seeming to be necessary to produce it than when it occurs higher up. It may, however, be induced in an indirect manner, as when a person, falling from a considerable height, alights upon his foot or knee, the violence of the shock being concentrated upon the inferior portion of the femur.

Treatment.—The treatment of fractures of the shaft of the thigh-bone may be conducted according to several plans, of which that by extension and counterextension, the limb being in the straight position, is, as a rule, the most eligible, fulfilling, as it does, more effectually than any other, the different indications presented by this class of injuries. Before any steps, however, are taken to adjust the broken pieces, a suitable bed must be procured for the comfortable accommodation of the patient, as well as for the secure management of the case. This subject having been fully discussed in a previous part of the work, it will be sufficient, for my present purpose, merely to allude to it here, with the hope of enforcing more fully its importance. I am so thoroughly convinced of the utter impossibility of treating fractures of the femur successfully without a good bed, that I should consider any surgeon justifiable in declining to undertake the management of any case unless his efforts are properly seconded in this respect. There must be no compromise upon the subject; for, if the cure turn out badly, no allowance will be made by the patient and his friends for any deficiencies, shortcoming, or want of coöperation on their part. The whole blame falls upon the professional attendant, it being very properly assumed that he ought to know better than any one else what the emergency demands, and he should, therefore, spare no pains to meet it. Every fracture-bed should have slats, a good, firm but elastic mattress, and arrangements for the evacuation of the bowels, so that the patient may not be compelled to rise when he wishes to relieve himself. These essentials are all admirably combined in the ingenious and well-known contrivances of Dr. B. H. Coates, Dr. Addinell Hewson, Dr. E. Cutter, and others.

When both thighs are broken, or even when only one is affected, Jenk's fracture-bed, represented in fig. 558, will be found extremely convenient, both for evacuating the bowels and for making up the bed. It is thus described by Dr. Gibson:—

Fig. 558.
Jenk's Fracture-bed.

"It is composed of two upright posts about six feet high, supported each by a pedestal; of two horizontal bars, at the top, somewhat longer than a common bedstead; of a windlass of the same length placed six inches below the upper bar; of a cog-wheel and handle; of linen belts, from six to twelve inches wide; of straps secured at one end of the windlass, and at the other having hooks attached to corresponding eyes in the linen belts; of a headpiece made of netting; of a piece of sheet-iron twelve inches long, and hollowed out to fit and surround the thigh; of a bed-pan, box and cushion to support it, and of some other minor parts."

For the purpose of securing quietude of the limb, and accuracy of apposition of the ends of the fragments, numerous contrivances have been devised, all possessing, apparently, more or less merit, and yet not one of them being so perfect as to be wholly unexceptionable. A bare description and delineation of all the fracture apparatus now before the profession would form a stately volume. The surgical cabinets of some of our

medical schools contain cart-loads of such material, most of it as effete as the contents of a curiosity shop. Much of this apparatus has been patented, and extensively distributed by the inventors. The character of most of it is familiar to me, and I do not hesitate to declare that a large proportion of it is most villanous. The great and fundamental principles which every contrivance of the kind must necessarily possess are enjoyed by all, although in different degrees of perfection, and it cannot be doubted that the constant multiplication of such machinery, and the implicit confidence reposed in it by the younger members of the profession, are a prolific source of the many disastrous results which so frequently attend the treatment of fractures of the thigh. I have long been satisfied that the more simple the apparatus is, the more easily it is managed, and the more likely to prove efficient. With a proper knowledge of what is needed, and a little ingenuity on the part of the surgeon, the requisite means for the successful management of almost every case of fracture of the femur, however bad, may generally be provided either upon the spur of the occasion, or within a reasonable time after the occurrence of the injury. The plaster splint now coming into general use is one of the best of the many modern contrivances.

The apparatus at one time so extensively employed in this country was that of Desault, as modified and improved by Physick, consisting of one long splint, fig. 559, extending from below the sole of the foot to the axilla, and of a short one extending from the same point to the perineum. They are connected below by a transverse bar, for receiving the extending bands, and along the leg and thigh by strips of bandage. The counterextension is effected by a suitable thigh belt, the ends of which are passed through the mortise holes near the upper end of the splint. The apparatus is, however, an awkward one, constantly subject to derangement, and the results obtained by its aid are by no means so gratifying as they should be. It has always been found extremely unsatisfactory in my practice, and I have, therefore, for many years, never employed it in a single case, having given the preference to the fracture-box, represented in fig. 560. This box, which I used, for the first time, upwards of

Fig. 559.

Physick's long Splint.

Fig. 560.
Fracture-box with Side Splints.

forty years ago, extends from the tuberosity of the ischium to a level with the sole of the foot, which rests against the vertical piece, provided with two slit-like holes for the passage of the extending bands. The posterior surface of the box is hollowed out for the more easy accommodation of the thigh and leg, while the side pieces, fastened by hinges to the horizontal one, project so as to come to a level with the surface of the limb in front. To the outside of the box is secured a movable splint, about two inches in width, crutch-shaped and well padded above, and long enough to reach into the axilla, while another similarly arranged and constructed, is attached to the inside, being intended to press against the perineum. The whole apparatus is made as light as possible, and any intervals that may exist between it and the limb, after it has been properly adjusted, may be filled with cotton, tow, or, what is preferable, especially in compound fractures, wheat bran, the latter answering an admirable purpose, under such circumstances, not only affording an agreeable protection to the broken bone, but absorbing the discharges and preventing the development of maggots, which are so liable to form in such cases in hot weather. In changing the dressings, all that is necessary is to let down the sides of the box, the extension being, in the mean time, kept up, if necessary, by an assistant having hold of the foot. A broad leather splint, or one of binder's board, extending from the groin to the knee, should cover the thigh in front; it should be accurately moulded to the parts, and be firmly secured in its place with pieces of tape encircling the box.

Instead of the fracture-box now described, use may be made of two splints, one of binder's board and the other of wood, the former, which is intended for the inside of the thigh, reaching from the groin to the knee, while the other, placed along the outside of the limb, extends as high up, on the one hand, as the crest of the ilium, and, on the other, as low down as four inches below the level of the sole of the foot. These splints being well padded, are secured with an ordinary roller, the adhesive strips being attached to the inferior extremity of the long one, in order to keep up the requisite degree of extension.

Adhesive plaster is now universally employed in this country, both for maintaining extension and counterextension in fractures of the thigh, and is unquestionably a great improvement upon the means heretofore in use, as it tends not only to preserve the ends of the fragments in better and closer union, but, what is of great moment to the patient, prevents the pain, chafing, and ulceration which so frequently attended the old methods. The treatment is equally serviceable in simple and in compound oblique fractures of the lower extremity.

In a remarkable case of compound fracture of both thigh-bones, in a boy eleven years of age, under the care of the late Dr. Gilbert, an excellent cure was effected by the appa-

Fig. 561.

Gilbert's Fracture Apparatus.

ratus represented in fig. 561, aided by adhesive plaster. A long splint was stretched along the outside of each limb, from a few inches below the sole of the foot to within a short distance of the axilla; the extending strips, tied under the sole of the foot, and secured to a horizontal block, were controlled by a tourniquet; while the counterextending strips were carried along the pelvis, both in front and behind, and firmly fastened by transverse bands passed around the hip-bones, the back, and abdomen. The dressing was removed on the forty-fifth day.

Fig. 562.

Hodge's Method of Counterextension in Fracture of the Femur.

A valuable addition to the long splint, affording increased means for making counterextension, was suggested by the late Dr. H. Lenox Hodge. It consists, as will be seen by reference to fig. 562, of a bar of wrought iron, secured to the outer and upper part of the splint by bolts with movable nuts, and bent to the right or left, in accordance with the side to which it is applied. The splint should be sufficiently wide above to permit the rod, which terminates in a horizontal hook, about six inches in length, to pass clear of the patient's arm and shoulder. A long strip of adhesive plaster, at least two inches and a half in breadth, is extended along the front of the body from the pelvis to the top of the shoulder, and thence down the back to the buttock, leaving, as it crosses the shoulder, a short loop, in which is placed a small block of wood, fastened by means of a tape to the hook of the bar. To prevent the long strip from becoming detached, the body is completely encircled, at different heights, by three horizontal bands.

The advantages of this contrivance are that the extension and counterextension are made in a straight line, that the dressings maintain their place much longer than the ordinary ones, and, lastly, as the patient cannot sit up in bed, there is less danger of dis-

placement of the ends of the broken bone. To impart efficiency to the apparatus a foot-board should be added.

The *anterior splint*, as it is called, invented by the late Professor N. R. Smith, often yields excellent results in the treatment of fractures of the thigh, especially in the more complicated ones. It consists, as seen in fig. 563, of a single piece, made of wire, of the

Fig. 563.
N. R. Smith's Anterior Splint.

size of a No. 10 bougie, and bent at each extremity, the whole representing the form of a long parallelogram, three inches wide above, and two inches and three-quarters below. It must be long enough to reach from a point a little above the anterior spinous process of the ilium to an inch beyond the toes, when the thigh, leg, and foot are extended, three feet eight inches being a good average length for adults. The side-pieces are firmly connected by cross-pieces at a distance of about eight inches from each other. Thus constructed, the wire frame is easily bent to suit the case in hand. The angle at the tibio-tarsal joint, six inches from the extremity, is about 120°, to secure an easy posture for the foot; that at the knee and the one at the hip are each about 160°, the latter being seven inches from the upper extremity.

The splint, properly padded or tightly wrapped with a muslin bandage, and secured to the limb by a roller extended from the toes upward, is suspended by means of a pulley, cord, and hooks to the ceiling, as represented in fig. 564, a compress being placed upon

Fig. 564.

N. R. Smith's Apparatus applied to the Limb.

the instep and another upon the groin, to ward off pressure. The proper position of the hooks is a matter of great consequence. In general, the upper one should be attached nearly over the seat of the fracture, and the lower a little above the middle of the leg, the object being the thorough equalization of the pressure of the splint. The roller, con-fining the apparatus, should be well stitched to prevent it from slipping, or, what is better, wet, with a solution of silicate of sodium, and great care should be taken that it do not make undue constriction. This apparatus, which is exceedingly light and comfortable, is equally well adapted to fractures of the thigh and leg, in every portion of their extent.

The late Professor Hodgen, of St. Louis, used with great success a wire suspension splint, the bars of which are traversed by cotton sacking for the more easy and equable sup-port of the limb. The apparatus, depicted in fig. 565, is particularly adapted to the treat-ment of compound fractures of the lower extremity.

The mode of treating fractures of the thigh, originally suggested by Dr. Gurdon Buck, is now generally pursued in this country in most cases in which confinement in bed is necessary, and every surgeon of experience can bear testimony to its great excellence.

The long splints are entirely dispensed with, the extension being made by the action of a weight and pulley, and counterextension by the usual perineal strap lengthened out and fastened to the head of the bedstead. A strip of adhesive plaster, from two and a half to three inches in width, is stretched along each side of the limb, to a short distance above

Fig. 565.
Hodgen's Suspension Apparatus.

the knee, and confined with a roller extended from the toes up, the middle of it forming a loop below the sole of the foot. A thin block of wood, the width of the plaster, and long enough to prevent pressure over the ankle, is inserted into the loop, and thus serves

Fig. 566.
Levis's Extending Apparatus with Pulley and Weights.

to receive the extending cord, which is fastened to an elastic rubber band passing around the block, and playing either over the footboard of the bedstead, or, if there is no footboard, over a temporary frame, perforated at a height of about five inches above the level of the mattress, or, what is better, an adjustable clamp, holding in position the rod which supports the pulley, as seen in fig. 566. The thigh, at the seat of fracture, is surrounded with short splints, the heel is supported upon a thin, wedged-shaped hair cushion, and a bag, filled with sand, is placed along the outside of the leg and foot to prevent rotation. The amount of weight employed must be determined by the age of the patient and the other circumstances of the case. A child under eight years of age will seldom require more than five or six pounds, while an adult may require from fifteen to twenty, the substance being shot, iron, or sand. The most suitable perineal band is a piece of India-rubber tubing of one inch caliber, two feet in length, with a ring at each end, stuffed with bran or cotton lampwick, and covered with canton flannel, wrapped spirally round it, and renewed whenever it becomes soiled. The apparatus of Dr. Buck is represented in fig. 567.

The treatment of fractures of the thigh, introduced by Dr. Swinburne, recommends itself by its simplicity and efficiency. It consists, as will be seen by a reference to the annexed sketch, fig. 568, exclusively of extension and counterextension, without splints, the perineal and crural bands being secured to the bedstead, as in Dr. Buck's apparatus, and composed of similar materials. Free use is made of adhesive strips at the leg and foot, and also, if necessary, at the thigh. With such an arrangement the affected limb may be inspected or measured as often as may be desired, all danger of embarrassing the circulation is done away with, perfect cleanliness may be preserved, and any topical applications that may be required may be made and removed with the utmost facility. The advantages of this method are particularly conspicuous in complicated fractures of the thigh. Fractures of the femur and tibia treated in this manner leave very little, if any, shortening, except in the intracapsular form of the accident.

In addition to the contrivances here described and delineated for the treatment of fractures of the lower extremity, numerous others have been devised, some of which are suffi-

Fig. 567.
Buck's Fracture Apparatus.

ciently meritorious as to be worthy of special notice. Among these, two of the most valuable are those of Dr. Richard J. Levis and Dr. Thomas G. Morton. The subjoined drawings are so graphic as to render any description needless. Fig. 566 illustrates the apparatus of Levis. The pulley is secured by its shaft to the end of the bed, and receives

Fig. 568.
Swinburne's Method of treating Fractures of the Thigh.

the cord which is attached to the patient's limb. The weight consists of a number of perforated pieces, and is secured to the extending cord by means of a hook. Morton's apparatus, fig. 569, so extensively used at the Pennsylvania Hospital, is also very simple,

Fig. 569.
Morton's Extending apparatus for Fracture of the Femur.

and, like that of Levis, fulfils every indication for which such a contrivance can be employed.

Finally, counterextension may advantageously be made by elevating the foot of the

bedstead, so as to allow the patient's body to sink into the upper part of the bed, and thus, by its weight, draw the superior fragment away from the inferior. This mode of treatment, in which a perineal strap is rendered unnecessary, was extensively practised during our late war, and its efficiency is undeniable, as every experienced surgeon can testify from personal observation.

Whatever apparatus be employed, whether those now described, or others of a similar character, there are several circumstances which should claim the special attention of the practitioner, particularly in the treatment of fractures of the shaft of the femur. The kind of bed to be used is described under the head of general treatment.

1. The ends of the broken bone must be steadily maintained on a line with each other, any tendency to angularity, lateral distortion, or tilting up of the fragments being promptly counteracted by pressure opposite the point of projection. This disposition manifests itself, more or less, in nearly all fractures of the femur, and should never for a moment be lost sight of, otherwise it may not be discovered until it is too late to remedy it. It is particularly strong when the lesion is situated from two and a half to three inches below the small trochanter, in consequence of the action, on the one hand, of the iliac and psoas muscles, and, on the other, of the external rotators ; the former, as before stated, tilting the lower end of the superior fragment forwards, and the latter outwards. For want of attention to this circumstance, wretched deformity of the limb is a frequent result of this injury.

2. No shortening must be permitted, and, therefore, constant vigilance must be exercised in regard to the tightening of the extending and counterextending bands. If any doubt exists, a comparative estimate must be made from time to time of the length of the two limbs, by stretching a piece of tape from the centre of the umbilicus to the centre of the inner border of each patella, or from the anterior superior spinous process of the ilium to the internal malleolus, the body and limbs lying perfectly straight.

3. A slightly everted position of the limb being the most natural when the body is dorsally recumbent, the surgeon should aim to maintain it in that way during the period necessary for the reunion of the ends of the broken bone.

4. The heel must be seen to ; if neglected, it will be sure to inflame and ulcerate, if not slough. Too much care, therefore, cannot be taken to ward off pressure by filling up the hollow on each side of the tendo Achillis with cotton, or by employing, if necessary, a small air-bag, or a bladder partially filled with water. The foot should always be well supported.

5. Extension must be maintained with two broad strips of adhesive plaster, stretched along the sides of the leg, previously shaved, to three inches above the knee, secured by cross-pieces, and fastened to the foot-board of the splints or fracture-box. Or, instead of this, two long, broad strips of muslin are secured to the limb by means of a roller, the upper extremity of each being turned, loop-like, down upon itself, over the bandage, and then properly fastened. The gaiter and handkerchief should be discarded from practice, for reasons previously mentioned.

6. The perineal band must receive due attention, otherwise it will be sure to gall and fret the parts, and thus greatly distress the patient. Besides, if not properly managed, it will be extremely liable to displace the upper fragment, by dragging it outwards, away from the inferior.

7. In compound fractures, one of the splints may be bracketed, as originally recommended, in 1813, by Dr. Hayes, of Indiana. The opening thus left permits ready access to the wound, and, consequently, great convenience for the application of the necessary dressing. The annexed cut, fig. 570, affords an illustration of an excellent apparatus of this kind, devised by Dr. John H. Packard, of this city.
Fig. 570.

Packard's Fracture Apparatus.

8. Great objection has been urged by certain writers against the employment of the bandage in the treatment of fractures of the thigh, on the ground that it is not only inconvenient, but absolutely useless. My experience does not corroborate this statement. On the contrary, I have always derived the most marked advantage from the bandage, both in controlling spasm, in counteracting the tendency to shortening, so common in nearly all cases of this kind, and in

promoting the absorption of inflammatory deposits. To answer the purpose, however, it must be applied with great care; otherwise harm, not benefit, will result.

In simple fractures of the thigh, the ordinary roller is sufficient; but in compound, preference is given to the bandage of Scultetus, inasmuch as, being composed of separate strips, it admits of more easy removal and reapplication.

The water-glass, starch, gum, or plaster bandage, may often be employed with great advantage, giving adequate support to the broken limb, and enabling the patient to take exercise in the open air, or about the house, upon crutches, a matter frequently of great importance. My experience, however, is averse to its use in the early stage of the treatment; applied too soon after the accident, before there is complete or nearly complete subsidence of inflammation and swelling, it may do incalculable harm, not only materially aggravating the local trouble, but endangering the safety of the limb by the induction of gangrene. For these reasons I seldom employ it before the end of a fortnight. In hospital practice, where the patient is under the constant surveillance of the professional attendant, the permanent dressing may generally be employed much sooner.

9. The bedclothes must be kept off the fractured limb, as their weight would not only be oppressive, but tend to derange the ends of the fragments. A good and ready mode of accomplishing this is to cut a stout barrel-hoop through at the middle, and to place the two halves, tied firmly together, crosswise, over the injured extremity. Or, instead of this contrivance, the surgeon may use, what is much better, the frame depicted at page 912.

10. It is very important, in the treatment of fractures of the lower extremity requiring extension and counterextension, that the patient's head and shoulders should not be raised high; a small pillow is generally quite sufficient, and, in some cases, even this may very properly be dispensed with.

11. Mr. Pott conceived the idea that the best mode of treating fractures of the femur was to place the affected limb upon its outside, the body inclining in the same direction, and the knee being in a semiflexed state. The leg and foot, supported upon smooth pillows, were elevated somewhat above the level of the thigh, which was enveloped by a many-tailed bandage, and covered in by two broad, carved wooden splints. This plan, which Mr. Pott recommended with all the enthusiasm of a man of genius, was based upon the erroneous notion that it would completely relax the different sets of muscles connected with the broken bone, thus preventing them from acting injuriously upon its fragments; forgetting that, in proportion as he took off the tension from one class, he necessarily increased that of another. It has been found to be altogether impossible to carry out this plan successfully in practice, experience having shown that the patient is utterly unable to remain so long in one position without suffering greatly from bed-sores, and that the apparatus, with all the care that can be taken to keep it in its place, is wholly inadequate to answer the purpose of an accurate adjuster.

12. Another mode of treating fractures of the body of the femur, very different from any hitherto described, was formerly much in vogue both in England and in this country, chiefly in consequence of the influence of the late Sir Charles Bell, by whom it was extensively employed for a long time at the Middlesex Hospital, London. It consists in placing the limb upon two grooved cushions, resting upon two pieces of board, united by hinges in the form of a double inclined plane, as seen in fig. 571, and long enough to

Fig. 571.
Double Inclined Plane of Sir Charles Bell.

extend from the tuberosity of the ischium to the back part of the heel. A roller having previously been applied from the toes to the groin, two light but firm binder's board splints, carefully softened in hot water, are secured to the outer and inner parts of the thigh, meeting nearly in front and reaching from the groin to the knee. The extremity

is now laid over the inclined plane, in an easy, comfortable position, the angle of flexion having special reference to this point ; the foot is attached to the foot-board, and the limb and plane being tied firmly together by tapes, or, what is better, by a bandage, the dressing is completed.

The method of treatment by the double inclined plane ought not to be too lightly condemned, for it cannot be denied that very excellent cures are occasionally effected with it. Much less frequently employed now than formerly, it is more particularly applicable to the treatment of fractures of the condyles of the femur and of the upper extremity of this bone, attended with a constant disposition to displacement of the lower end of the superior fragment. In transverse fractures immediately above the knee-joint, and in separation of the inferior epiphysis of the femur, the gastrocnemial muscles drag the lower fragment backwards into the popliteal space ; an effect which can only be counteracted by the flexed position of the limb, the leg, in the more troublesome cases, being bent almost at a right angle with the thigh. The double inclined plane may also be advantageously employed in compound fractures, attended with severe contusion and laceration of the integument, where confinement in the extended position would be productive of violent pain and great discomfort. The extension is made mainly by the weight of the leg and foot, while the counterextension is made by the pressure of the apparatus against the tuberosity of the ischium. The annexed drawing, fig. 572, represents McIntyre's splint, a double inclined plane, modified by Liston. Fig. 573 exhibits it as it is applied to the limb.

Fig. 572.

McIntyre's Splint, simplified and improved by Liston.

Fig. 573.

McIntyre's Splint applied to the Limb.

Finally, when both thighs are broken, the case may be treated with a double inclined plane, or a fracture-bed, the hinges being arranged in such a manner as to permit the trunk to be raised or lowered at pleasure, without causing any motion of the hips. The limbs should be well protected with side and front splints, and immovably tied together.

13. The period required for the consolidation of fractures of the shaft of the femur must necessarily be greatly influenced by circumstances, as the age and health of the patient, and the care with which the ends of the fragments are kept together. In children from five to fifteen years, complete union may usually be looked for in from twenty-four to twenty-eight days. In eighteen cases analyzed by Dr. A. L. Peirson, of Massachusetts, the cure, in persons of thirty years of age and under, occupied 35.88 days ; while in seventeen, where the age was upwards of thirty, the average period was 36.64 days ; thus showing only a very trifling difference in the two series. On no account should any weight be thrown on the affected limb under ten or twelve weeks. From a want of this precaution great shortening often results, especially in those cases in which the new osseous matter is slow in acquiring its proper density and firmness.

It has been asserted by many highly respectable practitioners that it is always extremely difficult, if not impossible, to effect a cure in fractures of the shaft of the thigh-bone without some degree of shortening, and my conviction is that this conclusion is only too well founded. There can be no question at all that in many cases a certain degree of shortening is absolutely and positively unavoidable, not on account of any defect in the treatment, but from the very nature of the fracture itself. How is it possible it

should be otherwise, when the ends of the fragments are driven the one into the other? The best skill and the most devoted attention would utterly fail, under such circumstances, to make a good limb. So, also, when a fracture is compound or comminuted, more or less deformity and shortening will almost be inevitable. In the New York Hospital, where fractures of the shaft of the thigh-bone are very common, and where this accident is probably treated with as much adroitness and care as anywhere in the world, from a third to half an inch of shortening is generally looked for, as a natural consequence, by the surgeons of that Institution, and it is questionable whether the statistics of similar establishments, if ascertainable, would exhibit a more favorable result.

In 149 cases of fractures of the thigh, reported by Dr. Buck, as having been treated according to the method which bears his name, the average shortening in patients under fifteen years of age was ⅜ of an inch, and ⅝ in those over fifteen years. In some of the cases there was no shortening whatever.

Professor Hamilton finds, as the result of his investigations, that the average shortening in simple fractures of the upper third of the femur is about four-fifths of an inch, and of the remainder of the bone, stated in round terms, three-quarters of an inch. He adds that, in oblique fractures of the shaft of the femur, in which the muscles retain their contractile power, no apparatus that has yet been devised can entirely prevent shortening; and the same, he remarks, is true of transverse, oblique, and denticulated fractures, in which the ends of the fragments have become completely deranged, owing to the impossibility of placing them in such relations as that they will rest upon and support each other during the time necessary for reunion. He further states that in children, and in persons under eighteen years of age, the cure is frequently so perfect as to render it impossible to discover any material shortening by measurement of the limb.

2. FRACTURES OF THE INFERIOR EXTREMITY.

Fracture of the condyles of the femur is, in comparison with fracture of the condyles of the humerus, an extremely infrequent occurrence. Indeed, it is very uncommon, not only relatively, but absolutely, speaking. Sir Astley Cooper mentions only two instances of the kind in his work on Dislocations and Fractures; the Dupuytren Museum at Paris, so rich in osteological preparations, contains but five specimens of the lesion; and in the Mütter collection, not a single bone, illustrative of the occurrence, is to be seen. The cabinet of Professor William Gibson, now in the Government collection at Washington City, has, however, several beautiful specimens of fracture of the condyles; and among my own preparations is a very rare one, in which these eminences are broken off vertically, leaving the trochlea attached to the lower end of the shaft, which exhibits a remarkably comminuted appearance, consisting of not less than five distinct fragments.

The fracture may be limited to one of the condyles, which, however, is extremely rare, or it may implicate both, the fissure in the latter case extending between the two prominences, and terminating above in an oblique fracture of the shaft, so as to give rise to three distinct fragments. From the amount of force required to produce this fracture, it is generally attended with a great deal of injury to the soft parts, and, for the same reason it is not unfrequently of a compound and comminuted character, the ends of the fragments protruding either externally or projecting into the cavity of the knee-joint. A partial fracture of one of the condyles occasionally occurs. In rare cases, the fracture presents the character of impaction, the lower end of the shaft being forcibly impelled into the cancellous structure of the condyles, which are completely severed in their entire length. Fig. 574 conveys an excellent idea of a fracture of the external condyle from a drawing of Sir Astley Cooper.

Whatever form the fracture may assume, it is nearly always the result of direct violence; generally of a fall upon the knee, the passage of the wheel of a carriage, or the kick of a horse. In one of three cases that have been under my observation, it was occasioned by a fall from a high scaffold, the individual, a man upwards of fifty years of age, alighting upon his feet, but striking, before he could recover himself, his knee against a large stone. The subjects of these fractures are usually old persons, in whom the condyles of the femur have become atrophied and brittle from the effects of interstitial absorption and fatty degeneration.

Fig. 574.
Fracture of the External Condyle.

The *symptoms* of fracture of the condyles are not always well characterized, owing to the fact that the fragments are generally held in place by the ligaments of the knee, thus preventing marked deformity, and rendering the production of crepitation difficult. The joint appears to be wider and flatter in front than usual, and, if the patella be pressed backwards, the condyles may be considerably separated, so as to increase the transverse diameter of the limb. The joint is much swollen and bruised, the member is completely powerless, and, when the fracture affects both prominences, there is nearly always marked shortening, often amounting to from one to two inches, the lower fragment being drawn up behind the superior by the action of the hamstring muscles. When only one condyle is broken, the deformity, other things being equal, will be less than when both suffer, and there will also, of course, be less shortening. Blood, often in considerable quantity, is generally poured into the joint in injuries of this kind, and more or less synovitis is an inevitable consequence.

In the specimen of vertical fracture of the condyles in my cabinet, previously alluded to, the short fragment is drawn upwards against the posterior surface of the shaft of the femur, to a distance of at least two inches, its upper surface looking towards the trochlea, with which it forms an obtuse angle, thus greatly increasing the antero-posterior diameter of the joint. The various appearances of this rare specimen are well represented in fig. 575.

Fig. 575.
Comminuted Fracture of the Lower Extremity of the Femur.

Fracture of both condyles occasionally simulates partial luxation of the head of the tibia backwards; and, when this is the case, the only way to determine the diagnosis is to take hold of the condyles, and to press them in opposite directions, which cannot be done when there is no fracture. The same proceeding can hardly fail to elicit crepitation, although this may be rather slight, especially if the fragments are held firmly together by the ligaments.

The prognosis of this fracture is especially grave, on account both of the injury done to the soft parts, and of its connection with the joint, which may be involved in an alarming degree. The fracture may, as already stated, be compound or comminuted, and, in such an event, the danger will, of course, be greatly increased, perhaps to such an extent as to require amputation, or, when this is not deemed advisable, in such a manner as to jeopard life by mortification, pyemia, erysipelas, or congestive pneumonia.

The *treatment*, in the first instance, must usually be strictly antiphlogistic, leeches and evaporating lotions being necessary, on account of the injury done to the soft parts. The limb, enveloped in a bandage, is laid in an easy position, being extended, if the fracture be transverse, or nearly so, and placed over a double inclined plane, if it be very oblique, with a strong tendency to displacement of the broken ends. Spasm, so common after such accidents, is allayed by anodynes, and an effort is made to prevent erysipelas and other bad consequences. When the tendency to displacement is uncontrollable by ordinary means, the best plan is to divide the tendo Achillis in order to counteract the action of the gastrocnemius muscle. Passive motion is instituted at the expiration of five or six weeks, but, despite the attention of the surgeon, a good, unexceptionable cure will be extremely difficult, if not impossible, especially when both condyles are implicated.

Complicated fractures of the condyles are generally the result of direct violence, as the passage of the wheel of a carriage, a fall from a great height, or gunshot injury, and are among the most dangerous of accidents, bringing life in jeopardy by tetanus, erysipelas, pyemia, profuse suppuration, and hectic irritation. The danger is proportionately increased when the lesion is attended with an extensive wound of the knee-joint, or a comminuted

condition of the bone. An attempt may be made to preserve the limb when the patient is young and in good health at the time of the fracture, when the weather is not too hot and exhausting, and when the injury in the soft parts is comparatively slight; under opposite circumstances the best plan, as a rule, will be to amputate immediately after the occurrence of reaction. To hesitate, in such a case, would only be to trifle with the patient's life, which could hardly fail to be the forfeit of the surgeon's timidity.

Examples of diastasis of the inferior *epiphysis* of the femur are occasionally met with. In a case observed by Coural, the accident happened in the act of falling forward at a moment when the leg was buried up to the knee in a hole.

Fig. 576.

The shaft of the femur was driven behind the condyles into the popliteal space, and there was such an amount of injury as to necessitate amputation of the limb. The patient was a boy, eleven years of age. Little, Voss, and Buck have reported similar instances. I have met with this accident not less than four times in attempts at breaking up the adhesions in ankylosed knees, and have never found any difficulty in effecting good and prompt cures by putting up the limb at once in appropriate apparatus. In most of the cases hitherto reported the accident was the result of such severe violence as to necessitate amputation. The injury has generally been of the nature of compound fracture, attended with extensive laceration of the soft parts. In one case the anterior tibial artery was torn open, and in another, related by Dr. Willis S. Davison, of Pennsylvania, the popliteal vessels were ruptured: in a few instances the knee-joint was exposed. In all such cases the prognosis must needs be unfavorable. When the injury is uncommonly severe, or the condyles are comminuted, great deformity may result, or shortening of the limb may take place from an arrest of development of the femur. The epiphyseal fracture is well illustrated in fig. 576, from Holmes. Such occurrences are, for obvious reasons, peculiar to young subjects before the twentieth year. Madame Lach-

Separation of the lower Epiphysis of the Femur combined with Fracture.

apelle saw a case of diastasis of the inferior epiphysis of the thigh-bone from traction on the child's foot during parturition. The lesion was conjoined with a separation of the upper epiphysis of the tibia.

3. FRACTURES OF THE SUPERIOR EXTREMITY OF THE FEMUR.

The superior extremity of the femur comprises the head and neck of that bone, together with the two trochanters, so that in an individual of ordinary stature it is from three inches and a quarter to three inches and a half in length, there being, however, no distinct boundary line between it and the shaft. The head composes nearly two-thirds of a sphere, and rests upon the neck, which is inclined obliquely upwards and inwards, so as to form an obtuse angle with it; they are surrounded by the capsular ligament, the strongest membrane of the kind in the body, and consist of a large amount of spongy tissue, inclosed by a thin lamella of compact substance. Both these structures undergo important changes with advancing age, the former becoming greatly rarefied, light, and porous, while the latter is so attenuated as to be, in some places, hardly as thick as common letter paper. These changes, the necessary effect of which is to render the bony texture frail and brittle, are particularly conspicuous after the fiftieth year, and readily explain the frequency of fracture of the neck of the femur at and after this period of life. There is another circumstance, also, which, doubtless, materially contributes to this accident, namely, the alteration which this portion of the femur undergoes in its direction in old persons, causing it, in many cases, to stand off almost at a right angle with the shaft of the bone, or even to sink slightly below this level. This alteration in the obliquity of the bone is, generally, more common, as well as more marked, in women than in men, and hence it is that the former are always more liable to this fracture than the latter. These various appearances are well illustrated in the adjoining sketches, fig. 577 representing the ordinary normal shape of the head and neck, together with its spongy and compact structures, while fig. 578, from a preparation in my collection, affords a good idea of the changes which these parts experience in consequence of the effects of age.

The ligaments of the hip-joint always sustain very grave injury in fracture of the superior extremity of the femur. When the lesion occurs within the articulation, the capsule is always torn across, the rent being frequently so large as to permit the escape of the upper extremity of the lower fragment, either at the moment of the accident, or

Fig. 577.

Fig. 578.
Natural Appearances of the Head and Neck of the Femur.

Alterations of the Head and Neck of the Femur from the Effects of Old Age.

soon after, thus accounting for the great shortening which is so often witnessed. The upper fragment, representing the head and a portion of the neck of the bone, on the contrary, remains attached to the round ligament, which thus supports and nourishes it, its supply of blood and nervous fluid being cut off in every other direction. This circumstance alone is sufficient to account for the fact that such a fracture cannot unite by osseous matter; but there are two other causes which powerfully contribute to such a result, the imperfect development of periosteum, and the large quantity of synovial fluid which is always poured out in the intracapsular fracture, the former disqualifying the fragments for the formation of callus, and the latter opposing their union.

Fractures of the neck of the femur are divisible into two classes, those which occur within the capsular ligament, and those which take place exterior to it; the former being now usually termed intracapsular, the latter extracapsular. The distinction is one of great pathological as well as practical importance, and is, therefore, worthy of profound consideration.

INTRACAPSULAR FRACTURES.

Fracture of the neck of the femur within the capsular ligament may occur at any portion of this part of the bone, as exhibited in the accompanying figs. 579, 580, and 581; but, in general, it is met with at a short distance below the head, or between the head and centre of the neck, where the compact structure is unusually weak, and where, consequently, the slightest force frequently produces the accident. Sometimes the line of fracture is on a level with the globular head, which, therefore, alone constitutes the upper fragment; and, on the other hand, cases are observed where the bone yields just above the attachment of the capsular ligament. Finally, the fracture is sometimes, although very rarely, partly within and partly without the ligament, forming an interesting variety, especially in reference to the question of the process of consolidation.

The direction of the fracture is usually more or less oblique; a strictly transverse fracture is a very uncommon occurrence; in rare cases, the bone is comminuted, as in a specimen in my private collection; and, now and then, the fracture is impacted, the upper extremity of the lower fragment being thrust into the cancellous structure of the superior. The head of the bone occasionally suffers along with the neck. The ends of the fragments are generally very sharp pointed, or spiculated.

An incomplete variety of intracapsular fracture is sometimes, although seldom, met with, a portion of the compact structure retaining its integrity, while the remainder yields under the force of the exciting cause of the accident. Again, instances occur in which, the fracture being complete, the ends of the fragments are temporarily retained

Fig. 579.   Fig. 580.

Illustrations of Intracapsular Fractures.

in apposition by the periosteum, thickened, perhaps, by inflammatory or ætal changes. A well marked example of an incomplete intracapsular fracture has been reported by Dr. J. B. S. Jackson, of Boston, as having happened in a man forty-two years of age, in consequence of a fall through two stories of a building upon a hard floor, breaking his spine and femur at several points. The fracture of the neck, commencing at its junction with the head, reached, as seen in fig. 582, nearly in a perpendicular direction, to within about a quarter of an inch of the inferior and internal wall of the bone, the fissure being so extensive that, if the man had been able to walk, the unbroken part could probably not have supported the weight of his body.
Fig. 581.   Fig. 582.

Intracapsular Fracture of the Femur.   Vertical Fracture of the Neck of the Femur.

The cause of intracapsular fracture is generally some trivial accident; most commonly a fall upon the great trochanter, or a blow upon the hip when the thigh is fixed and separated from its fellow, thus increasing the strain upon the upper portion of the bone. I have known the injury to be produced by the great toe catching in the fold of the carpet, while the person, an old lady of seventy-six, was walking across the floor.   In London, according to Sir Astley Cooper, it most frequently occurs from the foot suddenly

slipping off the edge of the side-walk over the curbstone, upon the horse pavement, the weight of the body being thus thrown forcibly upon the neck of the bone in a perpendicular direction, when it is unprepared for such an event. The fracture may also happen in turning awkwardly in bed, or in stepping carelessly out of bed upon the floor, the individual in either case powerfully twisting the thigh-bone. The fact that so serious a lesion may arise from so trivial a cause, while it is of great value in a diagnostic point of view, affords the clearest possible proof that a bone, liable to be so affected, cannot be very sound, but that, on the contrary, its structure must have undergone serious changes to render it capable of an accident which, in other pieces of the skeleton, requires an extraordinary degree of force. That this is true, as a principle, has already been shown, the immediate cause being a fatty, atrophied, and rarefied state of the compact and spongy tissues of the neck of the bone, the animal matter being absorbed, and the earthy alone left, the result of the whole being a weakened condition of the affected parts, and, consequently, a predisposition to fracture. Although the lesion is usually occasioned by slight accidents, instances are observed in which the reverse is the case, and it is then ordinarily also of a complicated character.

The age at which this variety of fracture occurs is, diagnostically considered, a matter of great importance. A fracture in other bones, or parts of a bone, may take place at any period of life, even in infancy and early childhood. Thus, I have seen the shaft of the femur itself broken in an infant of four weeks. But it is very different with the neck of this bone within the capsular ligament, experience having shown that it is subject to fracture only, as a rule, after the age of fifty, when, as already stated, its spongy and compact tissues suffer from atrophy and fatty degeneration, thus rendering it more or less brittle, and incapable of withstanding injury. The youngest subject in whom I have witnessed this fracture was a lady thirty-four years of age, the injury having been caused by a fall upon the hip; Mr. Stanley observed an instance at nineteen; Dr. William Hunt one at twenty-five; Bryant at twelve; and Dr. H. Wardner, of Illinois, one at fourteen. All such cases are, however, exceptional. The oldest subject in whom I have met with this fracture was a lady of ninety-four. The accident happened in a fall from her chair upon the floor, her general health being much impaired at the time. In Hunt's case the patient died from the effects of other injuries, and the dissection revealed the existence of a transverse fracture in the cervix immediately above the attachment of the capsular ligament. The accident took place in a railway train.

Sex also exerts a considerable influence upon the production of intracapsular fracture. Of its precise relative frequency in males and females, no reliable statistics, at least none upon a large scale, have been placed before the profession, although a sufficient amount of information has been obtained to justify the assertion that it is more common in the latter than in the former. In the tables of Mr. R. W. Smith, in his Treatise on Fractures, the sex is given in 28 cases, of which 17 were women and 11 were men. The cause of this difference appears to be twofold, the more horizontal position of the neck of the femur and the greater amount of atrophy and fatty degeneration of this portion of the bone in old females than in old males.

The intracapsular fracture may be complicated with fracture of the neck on the outside of the capsular ligament, the lines of disjunction running into each other. Such an occurrence, indeed, is not infrequent. Again, an intracapsular fracture may be associated with a fracture of the great trochanter; but this is extremely rare. In twenty-three specimens of this lesion in the Dupuytren Museum, at Paris, there is not a solitary example of such a coincidence.

The *symptoms* of intracapsular fracture are deserving of particular attention. They are: 1. Shortening of the thigh. 2. Eversion of the foot. 3. Preternatural mobility. 4. Crepitation. 5. Change of situation in the great trochanter. 6. Pain at the site of injury. 7. Peculiarity of the patient's body in the erect posture.

The *shortening of the thigh*, or of the limb through the thigh, is one of the most striking phenomena of this variety of fracture, and is the more valuable because of its almost universal occurrence. It is usually the first circumstance that attracts the attention of the surgeon, whether the patient is lying on his back or standing up. As might be expected, it varies in different cases and in different conditions of the same patient, its extent being greatly influenced by the state of the capsular ligament, being generally less in proportion to the integrity of this membrane, and conversely. It is always less immediately after the occurrence of the injury than it is after the lapse of several days, and also in impacted fracture than in the ordinary form of the accident. The amount of instantaneous shorten-

ing ranges from half an inch to an inch ; it may, however, be considerably less than this, not, perhaps, exceeding three lines ; and, on the other hand, it may reach an inch and a quarter, and even an inch and a half, especially if there be extensive laceration of the capsular ligament.   During the progress of the case, the shortening not unfrequently amounts to upwards of two inches, and in rare instances it has been known to exceed even three.

The diminution in the length of the limb, although generally immediate, is not always so, depending, perhaps, not so much, as has usually been supposed, upon the integrity of the capsular ligament, as upon the want of separation of the ends of the fragments, due to their peculiar denticulated condition, the incompleteness of the fracture, or the thickened and untorn condition of the periosteum, all tending to favor temporary contact of their surfaces.   It is hardly reasonable to imagine that, if the integrity of the capsular ligament were the only cause of it, this ligament would become so stretched or torn within so short a time after the accident as to admit of the amount of shortening above mentioned.   We must, therefore, seek for some other cause, and I know of none that is so plausible as the one here suggested.   Under such circumstances, the shortening generally takes place suddenly ; perhaps after the patient has made considerable exertion with his limb, several days, it may be, after the accident, from the instantaneous unlocking of the ends of the fragments.   When the fracture is impacted, the shortening will, of course, be immediate, and will also be likely to be permanent, unless the broken pieces be pulled forcibly asunder by the surgeon in the examination of the limb, or by the patient in his efforts at walking, sitting, or turning in bed.

Eversion of the foot, or rather, of the whole limb, is another striking symptom, seldom absent in any case.   When the patient stands up, it is such as to cause the heel of the affected side to point towards the hollow between the ankle and tendo Achillis of the sound limb ; while, when he is recumbent, the foot inclines outwards almost horizontally, dropping involuntarily upon its external surface, nearly or quite in contact with the floor or bed.   The eversion, although generally an immediate effect of the accident, does not always reach its maximum until some time after, depending upon the manner in which the ends of the fragments are held together.

The cause of the eversion is generally supposed to be the action of the external rotator muscles, which, as they are connected with the superior extremity of the bone, readily roll the thigh outwards when, from any circumstance, it has lost its support above, the irritation consequent upon the fracture being an additional incentive to contraction.   My own opinion, however, is that, although the external rotator muscles may not be wholly inoperative in the production of this occurrence, it is generally due, in a very great degree, if, indeed, not wholly, to the weight of the limb, the natural tendency of which is to eversion whenever it is free from restraint as the patient lies on his back.   In the impacted fracture, this symptom may be entirely absent, or, in other words, the limb, instead of being turned out, may be inverted ; and a similar occurrence is occasionally, although rarely, noticed in an intracapsular fracture, due, apparently, to the action of the adductor muscles of the thigh, aided, perhaps, by a rent in the inner portion of the capsular ligament ; or, if we adopt the explanation of the late Mr. R. W. Smith, of Dublin, to the manner in which, in such an event, the lower fragment is drawn up in front of the upper.   Examples of this occurrence have been recorded by Guthrie, Langstaff, Stanley, Cruveilhier, Hamilton, Hudson, Bigelow, and others.   A few cases have also been met with in which the foot pointed directly forwards, the limb being neither everted nor inverted.   Finally, it is possible, as Mr. Erichsen has stated, that cases may arise in which the inversion of the limb in an ordinary fracture may be due to paralysis of the muscles on its outer side.

Preternatural mobility, common to all fractures, is particularly observable in the intracapsular variety, and, therefore, serves as an important diagnostic sign of the accident. There are cases, however, in which it is absent ; in some entirely, as in the impacted fracture, and in others only in the early stage of the injury, as when the ends of the bone are held partially together by the interlocking of their fibres, by the incompleteness of the solution of continuity, or by some other cause.   Its existence, as well as its degree, is always readily ascertained by taking hold of the limb and rotating it upon its axis, or flexing it upon the pelvis, extending it behind the line of the sound limb, or carrying it inwards or outwards ; movements which cannot be executed when there is a dislocation of the head of the femur.   Extension and counterextension will have the effect of restoring the limb promptly to its proper length, but as soon as the forces are discontinued the original shortening is reproduced.

Crepitation, the most valuable sign of all in fractures generally, is rarely wanting in this. Indeed, it can only be absent in the impacted form of the lesion, or in those rare cases where the ends of the fragments remain still partially in apposition with each other. It is usually discoverable immediately after the accident, and may, of course, be elicited as long as the fracture continues ununited. In order to determine its existence, it is necessary to bring the ends of the broken bone fully into contact by extension and counter-extension, when, upon rotating the limb, it will at once declare itself, although in many cases it is very faint.

Change of position in the *great trochanter* is always a symptom of much importance in intracapsular fracture. This bony prominence is not only drawn upwards towards the ilium, but it is brought in close contact with the border of the acetabulum, and is, therefore, much less easily felt and seen than in the normal state, in which it is always so conspicuous. Moreover, when the thigh is rotated upon its axis by taking hold of the foot, the great trochanter will be found to turn, as it were, upon a pivot, or to move in a segment of a lesser circle than natural. From the circumstance of the limb being generally strongly everted, the portion of the broken neck attached to the trochanter is directed inwards and upwards, and is thus placed in closer proximity with the anterior superior spinous process of the ilium than the trochanter itself.

Another sign upon which much stress is laid is the condition of the fascia lata. In the natural state this fascia is in a state of tension; but in fracture of the neck of the thigh-bone it is, as was first pointed out by Dr. Allis, invariably more or less relaxed between the great trochanter and the crest of the ilium.

To determine the existence and the amount of shortening in fractures of the neck of the thigh-bone, Mr. Bryant's test-line, as it is termed, will be found to be of great value.

Fig. 583.
The ilio-femoral rectangle *a c b*. *c b* test line for fracture or shortening of the neck of the thigh-bone.

"For purposes of demonstration," says the English surgeon, "I have described it as the base of the ilio-femoral triangle, *c b*, fig. 583, the two sides of the triangle being made up of two lines drawn from the anterior superior spinous process of the ilium, one of them, *a c*, being vertical, and traversing the outside of the hip to the horizontal plane of the body; and the second, *a b*, impinging on the tip of the trochanter major and corresponding in the normal condition of the hip-joint to the anterior half of Nélaton's test-line for dislocation of the head of the femur backwards.

"The 'test line' *c b* for fracture or shortening of the neck, joins the two at *right angles* to the vertical line, and extends from it to the trochanter.

"Any shortening of this line, on comparing it with the same taken on the uninjured side, indicates with precision a shortening of the neck of the thigh-bone; and, when the shortening has followed at once upon an injury, fracture of the neck of the thigh-bone, impacted or otherwise, is certain. Compared with this line, all other measurements are uncertain. By its use, manipulations of the injured limb are often rendered unnecessary. For practical purposes, the vertical line *a c* and the test line *c b* are alone required. To compare the two sides of the body, it is necessary to see that the pelvis is straight."

Pain at the site of injury, being common to all fractures, is of special value only in connection with the other symptoms already described. It derives its chief importance from the fact that it is located at the upper and inner part of the thigh, in the direction of the small trochanter, and that it is always greatly increased whenever an attempt is made to rotate the limb, to bend it upon the pelvis, or to carry it inwards over the sound one. When the patient is perfectly quiet, with the limb in a relaxed position, the suffering is usually very trivial, except when the bone, in addition to the fracture, has been severely concussed or contused, when the pain will frequently be excessive. It is generally worse, too, at night than in the day, and in wet weather than in dry.

There is a peculiarity in the patient's *attitude* as he stands up, which cannot fail to strike the most careless observer. The body, in this position, is inclined forwards in such a manner as to throw its weight upon the sound limb, which is firmly planted upon the floor, while the other hangs off in a constrained, unseemly, and awkward manner; the foot and knee are strongly everted; the leg is supported upon the ball of the toes, while the heel, resting in the interval between the ankle and tendo Achillis, is elevated from

two to three inches from the surface; the natural prominence of the hip is destroyed; and the least attempt to walk or to raise the limb not only proves abortive, but is productive of exquisite pain.

Finally, there is seldom much *swelling* in this variety of fracture; it is only when the hip has been struck a severe blow that the superficial parts are likely to be the seat of any considerable effusion, ecchymosis, discoloration, or contusion, and even then the symptoms are usually very evanescent.

The *pathological changes* in intracapsular fracture vary very much, according to the period of the examination, as well as the character of the original injury. In recent cases there is usually some sanguineous effusion, although the quantity of blood is generally very small, unless, as occasionally happens, there is extensive rupture of the capsular ligament, when it may be considerable. Most commonly the ligament preserves its integrity, but if the accident has been unusually severe it may be torn at one or more points, so as to admit of the partial escape of the inferior fragment, the soft covering of which is often partially detached, hanging off in loose, irregular shreds. If several days have elapsed since the receipt of the injury, the synovial membrane will be observed to be unnaturally vascular, and slightly coated with plastic matter, a small quantity of which is also sometimes found upon the ends of the fragments. There is likewise, at this stage, a marked increase of synovial fluid, and the structures around the joint frequently exhibit a contused appearance, with more or less infiltration of blood and serum.

If the dissection be made after the lapse of some months, the capsular ligament will be found to be much thickened by interstitial deposits, as well as by the addition of plastic matter to its synovial lining; the head and neck of the bone are also incrusted with lymph; and the ends of the fragments are softened, unnaturally vascular, and rounded off, or partially connected by fibro-ligamentous bands. The interarticular ligament retains its normal structure, except in rare cases, in which it is inflamed and changed into fibrous tissue.

In old cases, or such as have lasted for some years, there are not only great thickening and induration of the capsular ligament, but extraordinary alterations in the broken bone, the neck of which is often completely annihilated, the shaft terminating abruptly on a line with the two trochanters. At other times the neck is converted into a short, conical knob, partially incrusted with cartilage, or scooped out, as it were, into a cup-like depression. The trochanters themselves are occasionally a good deal changed in their appearance, especially the great, which is liable to be diminished in size and altered in configuration. The head of the bone generally retains its position in the acetabulum, but that portion of the neck which remained attached to it at the time of the accident is usually

Fig. 584.   Fig. 585.

Senile Atrophy of the Neck of the Femur.   Atrophy which might be mistaken for United Fracture.

totally absorbed; and cases occur, although rarely, where the entire fragment is either destroyed or represented by the merest possible remnant held in place by the round ligament. When the head is left, its lower surface is occasionally hollowed out into a kind of

socket for the reception of the rounded conical end of the lower fragment ; or the reverse obtains, the head being rounded off, and the lower fragment scooped out. In either event, the two extremities, continually moving upon each other, in time acquire a smooth, polished, eburnized character, the better qualifying them for the performance of their various functions.

The changes now described are sometimes closely imitated by those produced in the head and neck of the femur by a fall or blow on the hip, leading to interstitial absorption of the osseous tissue, and to shortening of the limb, with destruction of the articular cartilage and eburnization of the resulting stump, very much as in arthritic rheumatism. There is reason to believe that cases of this kind are not unfrequently mistaken, both during life and after death, for fractures of the neck of this bone. The appearances here alluded to are well illustrated in figs. 584 and 585.

The *mode of repair* of intracapsular fractures is peculiar. Ordinary fractures generally unite by osseous matter, but in this variety of injury the connecting medium is of a fibro-ligamentous nature, as in similar lesions of the olecranon process, the patella, and the skull. But it is not always that the surgeon is to look even for such a union, imperfect as it is; in many cases the ends of the broken bone utterly refuse to unite, being gradually rounded off, and, perhaps, slightly incrusted with cartilage, or, as not unfrequently happens, especially in very aged and decrepit subjects, becoming, in time, completely absorbed, the lower fragment disappearing as far down as the two trochanters, and the upper as high up as the brim of the acetabulum. In rare cases, indeed, even the entire head is removed, along with the greater portion both of the round and capsular ligaments.

Fig. 586.

Fracture of the Neck of the Thigh-bone, United by Fibrous Tissue.

A very excellent idea of the fibro-ligamentous union of this variety of fracture is afforded in fig. 586, from Sir Astley Cooper. It was taken nine months after the accident, from a patient between thirty and forty years of age.

The causes of this want of union are of easy recognition. In the first place, the parts have to encounter the prejudicial influence which results from the difficulty of maintaining accurate apposition of the broken ends of the bone; a circumstance which is so essential to the successful repair of fractures in other pieces of the skeleton, but which is almost impossible to effect here, in consequence of the want of proper leverage in the upper fragment. All the apparatus that has yet been devised for the purpose has utterly failed to accomplish the object; whatever may be done, more or less motion is inevitable. Secondly, the accident is always followed by a considerable degree of synovitis, and, as a necessary result, by an increased quantity of synovial fluid, which, bathing the ends of the bone, acts inimically to the consolidating process. Thirdly, the most important reason, however, of all, is the want of power in the parts to furnish the requisite amount of plastic matter from the injury sustained by their vessels and nerves at the time of the accident. The superior and smaller fragment, represented by the globular head of the bone, or the head and a little remnant of the neck, is solely dependent for its vascular and nervous supplies upon the round ligament, and every one who knows how small this ligament is, and how insignificant its vessels are in the natural state, must be aware how utterly inadequate it must be for the nourishment of the bone to which it is attached. It need not, then, be wondered at that there never is any osseous matter effused by this fragment. Nor does the inferior fragment fare much, if any, better in this respect. Destitute, in great measure, of periosteum, with many of its vessels in a hopelessly lacerated condition, its powers are too feeble to afford any substantial aid in the process of repair. Hence the result must necessarily always be as above stated; that is, there will either be no union at all, or, if an attempt is made at establishing a connection between the two fragments, that attempt will go no further than the formation of a fibro-ligamentous substance.

When no effort whatever at repair occurs, the ends of the fragments speedily undergo the fatty degeneration, and fall an easy prey to the action of the absorbent vessels, eventuating in their partial destruction or complete annihilation.

It would, perhaps, be going too far to deny altogether the possibility of bony union in

intracapsular fracture of the thigh-bone, and yet I have certainly never seen what I could regard as an unequivocal example of the kind.   I have examined most of the specimens in this country, purporting to be cases of osseous consolidation, and in no instance have the appearances been such as, in my opinion, to justify such a conclusion.   The history of these cases has generally either been so exceedingly defective, or the necroscopic characters have so closely resembled those witnessed in the changes which the head and neck of the femur undergo in consequence of old age or disease, as to destroy all confidence in their authenticity as genuine examples of intracapsular fracture.   I need not insist here upon the great difficulty which the practitioner frequently encounters in establishing a correct diagnosis in injuries about the hip; what skill and care are generally required to discriminate accurately between a mere sprain and a fracture, or a fracture and a dislocation; or how frequently even slight lesions of the ilio-femoral articulation, and of the head and neck of the femur, are followed by changes in the structure and conformation of these portions of bone which so closely simulate those produced by fracture as to deceive the most enlightened and cautious observer.

The question, then, in regard to the repair of intracapsular fracture, resolves itself into four groups of facts, which may be thus stated:—1. Under favorable circumstances, both as it respects the patient and the treatment, there may be fibro-ligamentous union, answering the purpose of a sufficiently strong bond to admit of tolerable progression after recovery from the more immediate effects of the accident.   2. Under adverse circumstances, that is, when the patient is old, decrepit, or worn out by disease, and cannot, in consequence, submit to proper treatment, or when, although the system is sufficiently vigorous, the case has been injudiciously managed, no consolidation whatever will take place, and not only so, but the neck of the bone, or both the neck and head, will be absorbed, the limb remaining, of course, permanently shortened and deformed.   3. Osseous union, although, perhaps, not wholly impossible, is yet so exceedingly infrequent that it cannot reasonably be looked for in any case, however propitious the circumstances attending it, both as it respects the patient and the skill and attention of his attendant.   The event, other things being equal, will be most likely to happen in the impacted form of the injury, and in the ordinary fracture in comparatively young and robust persons.   4. When the fracture is of a mixed character, that is, partly within and partly without the capsular ligament, the mode of repair will be similar to that of ordinary fracture, although the process will require more time and care for its successful completion.

The *prognosis* in this variety of fracture is embraced in the above remarks respecting its repair, and need not, therefore, engage further attention here.   In regard to life, the danger is generally inconsiderable, as the lesion is usually the result of very trivial accidents, involving no serious injury to the soft parts, or any comminution of the bone.   I have, however, seen several instances in old, dilapidated subjects, followed by death from shock, or shock and its effects.   In the case of an old lady ninety-four years of age, recently under my observation, death was produced by gradual exhaustion from excessive pain and want of appetite.   In regard to the limb, as the consolidation of the fracture is always more or less imperfect, its usefulness will necessarily be impaired in a degree proportionate to the defective character of the connecting medium.   For a long time the patient will be obliged to employ a crutch, but eventually he will be able to walk with the aid of a stick and a high-heeled shoe, the parts strengthening by exercise, notwithstanding there is a strong tendency to atrophy of the muscles.   The hip-joint generally remains permanently weak, and it is seldom that the patient does not experience more or less pain in it, often of a neuralgic, gouty, or rheumatic character.

Treatment.—Fractures of the neck of the femur within the capsular ligament are not, I think, generally so well managed as they should be, owing chiefly, if not wholly, to the influence of the writings of Sir Astley Cooper, who taught that, inasmuch as there never is any osseous union in this variety of injury, it is not, therefore, proper to torture the patient with a protracted confinement in the recumbent posture, and the application of an extending apparatus.   He considered such a proceeding the more necessary because a great majority of the subjects of this fracture are old and decrepit persons, many of whom bear confinement very badly, soon becoming affected with foul bed-sores, and eventually perishing from hectic irritation or congestive pneumonia.   In accordance with this view, he was in the habit of placing the limb upon a long pillow, in an easy position, for about a fortnight, or until the pain and inflammation, consequent upon the accident, had in great measure subsided.   The patient was then allowed to leave his bed, and sit in a high chair, or exercise upon crutches, care being taken to bear, at first, very gently upon the foot, for fear of disturbing and fretting the ends of the fragments.   Subsequently, as the limb

improved in strength, a high-heeled shoe was ordered, and a stick was substituted for the crutches.

If this treatment were the exception, and not the rule, every practitioner of sense and experience would concur in its propriety; but the English surgeon, in his desire to generalize it, has carried it much further than the interests of our patients justify. It is unquestionably true that many of the subjects of intracapsular fracture do not bear confinement well; they suffer from the slightest restraint, and soon become bedridden. Such cases are extremely difficult to manage, and are not likely to be benefited by the use of splints, or any other mechanical contrivances calculated to compress the limb and hold it in an uneasy and constrained position. To this class the treatment of Sir Astley Cooper is peculiarly applicable; indeed, no other can be employed. All that can be done is to make the patient comfortable, and let the limb get on as best it may. But there is another class of subjects, who, although perhaps a good deal advanced in years, are, nevertheless, quite stout and robust, enjoying excellent health at the time of the injury, whose constitution has never been impaired by intemperance or excess of any kind, and who can bear the long confinement incident to such an accident with the most perfect impunity. The persons composing this class are, for the most part, residents of the country, and not the poor, broken-down inhabitants of the crowded city, without any bodily vigor, or any recuperative power. Hence, no exclusive plan of treatment should be adopted; but the management should be varied according to the exigencies of each particular case. Such a course is the more necessary because it is utterly impossible always to determine positively, by the most careful examination, whether the injury is one purely of intracapsular or extracapsular fracture, or whether it partakes, as, indeed, it not unfrequently does, of the character of both, the two being conjoined.

Acting upon the above principles, I have, for many years, treated most of the cases of intracapsular fracture that have come under my notice as any other fracture of the femur, by permanent extension and counterextension, not with the hope, as already stated, of obtaining bony consolidation, but with the view simply of keeping the ends of the fragments more accurately in contact, and thus affording them an opportunity of becoming united by fibro-ligamentous tissue. It is obvious that such a result can only reasonably be anticipated when this condition is fully complied with. When the broken pieces are permitted to overlap each other constantly, hardly any union will be possible, certainly none of a useful kind; and there is, moreover, in such a condition, always great risk that at least the neck, if not also the greater portion of the head, of the bone, will be absorbed, and the patient, in consequence, never regain the functions of his limb. If the treatment fail, the surgeon has the consolation to know that he has discharged his duty, by having kept the parts in the only position in which it is ever possible for them to unite in any way. The thigh may be maintained in the extended position, and among the apparatuses

Fig. 587.

Daniel's Fracture-Bed.

which best fulfil this indication is that depicted at page 1009, extension and counterextension being made by the usual means. A splint of unoiled sole leather, well padded, and furnished with straps at the upper extremity, and carefully secured to the inner side of

the limb will be required to give due support to the ends of the fragments, or to prevent inward displacement. The splint should reach from the knee high up into the groin, inclose fully one-half of the thigh, be well fastened with a water-glass roller, and be attached by means of its two straps to a cord playing over a pulley with a weight of six, eight, or ten pounds, according to the age of the patient and the tendency to displacement. The object of this arrangement is to keep up a certain degree of lateral or oblique extension in order to effect and maintain more accurate apposition of the ends of the fragments than is possible by mere longitudinal extension. Good cures may also be obtained by placing the limb over a double inclined plane; or, what is better, when it can be procured, the patient may be put upon a Daniel's fracture-bed, represented in fig. 587. The latter contrivance, which, unfortunately, however, is too expensive for general private use, is particularly adapted to cases of old persons likely to require protracted confinement. The bed is so arranged that, while the patient can sit up, or vary his position, efficient extension and counterextension may be maintaned with adhesive strips. An elaborate description of the apparatus may be found in the tenth volume of the Transactions of the American Medical Association.

When a Daniel's fracture-bed cannot be obtained, a most excellent, as well as a comparatively cheap, substitute may be found in what is known as the Charleston reclining chair, fig. 588, modified and improved by Professor William H. Pancoast, the most important additions being a bed-pan and a movable footboard. The chair, made very strong and wide, is well stuffed, and arranged in the form of a double inclined plane, the patient, by means of pillows and other appliances, being thus rendered far more comfortable than he can be in any ordinary bed, the more especially as he can at any time shift his posture without any detriment to the affected parts. Professor Pancoast finds that this contrivance is peculiarly adapted to the treatment of fractures of

Fig. 588.

Reclining Chair.

the upper extremity of the thigh-bone in elderly subjects, having employed it successfully in a number of cases, with very little shortening of the limb in any. Apposition of the ends of the fragments is effected by means of compresses and short splints, confined by adhesive plaster and bandage, or the immovable dressing.

Whatever plan of treatment be adopted, its effects should be most carefully watched, so that it may not prove irksome, much less injurious. Particular care should be taken to see that the great trochanter preserves its natural prominence. Any flattening of the hip may be regarded as an evidence that there is inward displacement of the ends of the fragments, and danger of a want of ultimate reunion. The length of time during which the patient should be confined must vary, on an average, from ten weeks to three months and a half. During all this trying period he should be on a full allowance of meat and porter; at all events, upon a generous diet, in order to sustain the system and promote repair. Purgative medicines and all other depressing means should be used as sparingly as possible. Anodynes, if necessary, must be freely given in the evening to allay pain and procure sleep.

When the patient is able to move about he will derive great comfort from the use of a Willard's double hinge-joint apparatus, delineated in the section on tuberculosis of the hip-joint; one part corresponding with the thigh and the other with the hip and lower part of the trunk.

EXTRACAPSULAR FRACTURES.

The extracapsular fracture is situated at the base of the neck of the femur, extending from above downwards and from behind forwards in the direction of the intertrochanteric line. It is not always, however, as the name declares, strictly exterior to the capsular ligament; on the contrary, it occasionally passes above the attachment of that structure,

so as to partake of the character both of an inner and of an outer fracture of the neck, constituting what may be called a mixed fracture. Moreover, the injury is always associated with fracture of the trochanters, sometimes with one, at other times with both, thus leaving in the former case three fragments, and four in the latter. Again, the fracture is often comminuted independently of its connection with the trochanters; and in many instances it is attended with more or less penetration of the superior piece into the inferior. Observation, however, induces me to believe that, generally speaking, the penetra-

Fig. 589.   Fig. 590.

Extracapsular Fracture of the Femur.   Comminuted Fracture of the Upper Extremity of the Femur.

tion is very trivial, hardly ever exceeding three lines, and often not reaching even so high as that. Figs. 589 and 590 afford a good idea of the situation and direction of the extracapsular fracture.

In regard to the frequency of the occurrence of impaction in this lesion opinion varies. Robert W. Smith, of Dublin, asserts that all extracapsular fractures are, in the first instance, also impacted fractures; a statement which should be received with a considerable degree of allowance, for examples are certainly occasionally seen in which the reverse is the case.

The extracapsular fracture is not so common as the intracapsular; the difference, however, is trivial. Men are somewhat more subject to it than women, and, while it may take place at any period of life, experience teaches that by far the greater number of cases occur after the sixtieth year. It may be stated, as a rule, that a much greater amount of violence is required to produce this fracture than the intracapsular, but the rule admits of many exceptions. The most common exciting cause is a fall or blow upon the hip, in the direction of the great trochanter; it may also follow a fall upon the foot or knee, and the passage of the wheel of a carriage across the pelvis or upper part of the limb. Finally, cases occur where it happens from the body being crushed by a heavy load descending upon the back, the lower extremities being in a fixed state at the moment of the accident. In not a few instances, however, the fracture is occasioned by very slight causes, while in most there is reason to believe that the bone at the site of the lesion is in a remarkably brittle condition, predisposing it to the disruption of its fibres. In some of the preparations that I have examined in different osteological collections, the compact structure, although not very materially diminished in thickness, was almost of a vitreous consistence, while the spongy was extremely rarefied and expanded, thus occasioning great weakness of the part. The cervical portion of the bone, under such circumstances, frequently retains a remarkably healthy appearance. When the osseous tissue is so very fragile at this point, it is not improbable that it may occasionally give way under mere muscular contraction, as has happened in at least one well-authenticated case, the patient, a woman, eighty-three years of age, having met with the accident in an effort to preserve her equilibrium in the act of falling.

The *symptoms* of this variety of fracture bear a strong resemblance to those of the

intracapsular, some existing in a less, others in a greater, degree, but none, considered separately, possessing any diagnostic value.   In describing these symptoms it will be most satisfactory if they be presented in the same order as in the preceding case.

The *shortening*, which is a constant occurrence, varies from half an inch to an inch, as its minimum, to an inch and a half, as its maximum.   In exceptional cases it may, however, amount to two inches and upwards.   It is usually most distinct when there is a badly comminuted state of the bone, or when the great trochanter, forming a part of the upper fragment, is drawn uncommonly far outwards, so as to permit the lower fragment to ride considerably over the upper.   Moreover, it possesses the peculiarity of being generally as great immediately after the fracture as at any subsequent period.

The hip, as the result of these changes in the position of the great trochanter, is more or less flattened; and the femoral aponeurosis, as has been shown by Dr. Oscar Allis, will be found to be relaxed on the affected side when the patient stands up.

The knee and foot are generally *everted*, the limb lying as if it were perfectly powerless, the muscles having apparently lost all influence over it.   This symptom is even more striking than in the intracapsular fracture.   Eversion, however, is not so constant an occurrence as in the latter accident; in a considerable proportion of cases the limb is strongly rotated inwards, and in both varieties, but especially in the former, the displacement is occasionally so obstinate as to require an unusual degree of force to rectify it, depending, doubtless, upon the interlocking of the fragments.

The extracapsular fracture is characterized by complete *mobility* of its fragments, except when they are impacted, an occurrence which, as just stated, is more common here than in fracture within the capsule.   The loss of function is also complete, the patient being unable to lift the limb by the effort of his muscles, or to execute any of its natural movements.

The *crepitation* is generally very distinct, being often loud and cracking, and is readily perceived by the hand and ear, applied to the hip when the limb is rotated upon its axis. It is usually more marked than in intracapsular fracture, and does not, as in the latter, require extension and counterextension for its production.   When the fracture is badly comminuted, the fragments may often be readily detected with the fingers, and be made to move upon each other so as to emit a grating sound not unlike that caused by rubbing together several pieces of broken china.

The position of the great *trochanter* may be the same as in the intracapsular fracture, obeying the movements of the limb, and turning, as it were, upon a pivot, describing the segment of a lesser circle, as it does in the natural state.   In many cases, however, it is completely detached, and then, of course, it either remains stationary on rotating the foot, or it follows the inferior fragment as a separate body.   In general, it will be found to be somewhat farther off from the spine of the ilium than in the intracapsular fracture, depending upon the smaller amount of retraction of the limb.

The *pain* is always unusually severe, and is greatly increased by every attempt at motion and manipulation; it is more superficial than in intracapsular fracture, and is concentrated, as it were, upon the two trochanters.

The *swelling* is also uncommonly extensive, and there is nearly always considerable discoloration of the surface, owing to the contused and ecchymosed condition of the skin and subcutaneous connective tissue, the latter of which is often extensively infiltrated with blood.

The *attitude* of the patient possesses nothing peculiar; it partakes of the same general character as in intracapsular fracture, and, in fact, so closely simulates it as to be with difficulty distinguished from it.

Finally, along with the symptoms now described, there is generally, in extracapsular fracture, evidence of severe shock immediately after the occurrence of the accident, and the resulting reaction is not unfrequently followed by high fever, lasting often for a number of days, and requiring great attention on the part of the professional attendant.   In intracapsular fracture the patient may feel very faint, but he soon recovers, and has afterwards seldom much constitutional disturbance.

Repair of the extracapsular fracture is effected precisely in the same manner as in fracture of any other piece of the skeleton provided with periosteum.   It differs, therefore, wholly, in this respect, from that of the intracapsular form of the lesion.   Here osseous union is the rule, the want of it the exception, the reverse being the case in intracapsular fracture.   The period at which the consolidation is completed will, of course, depend, as a general rule, upon the age and health of the patient, the presence or absence of complications, and, above all, upon the care which is observed in keeping the ends of the fragments in accurate apposition.

Although the extracapsular fracture invariably unites by osseous matter, the *prognosis*

is very far from being always favorable either as it respects the possibility of avoiding deformity and lameness, or our ability to save the patient. When the fracture is comminuted, or the bone is broken into a number of pieces, including the two trochanters, a good result is hardly to be anticipated even under the most judicious management. Under such circumstances, the neck of the bone, having lost its support, is pushed downwards and inwards below its natural level, and a certain degree of shortening with deformity of the upper part of the thigh will be inevitable. The same result must necessarily follow when the fracture is impacted. These facts should be well studied and appreciated, and should always be promptly communicated to the patient, lest, when the cure is completed, he should blame his attendant for making him a bad limb when it was impossible to make a good one.

From the great violence that is so frequently inflicted upon the parts, both soft and hard, the extracapsular fracture often proves hazardous both to limb and life. Occasionally, although rarely, the patient dies from shock : in some instances he suffers greatly from the effects of excessive reaction. Most generally, however, when there is danger, life is put in jeopardy by the supervention of erysipelas or pyemia, the former commonly setting in within the first forty-eight hours from the occurrence of the fracture, and the latter towards the end of the first week or the beginning of the second. Some idea of the danger of extracapsular fracture may be formed when it is stated that, of eighteen cases treated in the Richmond Hospital at Dublin, nine proved fatal, the period of death ranging from the fifth to the fifteenth day. In some cases the patient sinks from the exhaustion consequent upon extensive suppuration or the formation of large sloughs over the sacrum and buttocks from protracted confinement in one position.

The *treatment* of extracapsular fracture differs in no wise from that which is necessary in fracture of the shaft of the bone. The limb, placed in the straight position, is kept perfectly at rest by means of splints, stretched along its outer and inner surfaces, and connected below in such a manner as to admit of the requisite extension and counterextension until a cure is effected. The foot should incline slightly outwards to favor relaxation of the external rotator muscles, and special care should be taken to prevent overlapping of the fragments, or angular deformity, by the use of a gutta-percha splint, accurately moulded to the outer and anterior part of the thigh, and well secured by the bandage. The dressing should be continued for at least six weeks.

IMPACTED FRACTURES OF THE NECK OF THE FEMUR.

Fracture of the neck of the femur occasionally presents itself as an impacted lesion, the lower extremity of the upper fragment being forcibly impelled into the cancellated structure of the upper end of the lower fragment, the great trochanter being usually carried along with the descending portion. The accident, which is sufficiently rare, and of which fig. 591, from a specimen in the Mütter collection, affords a beautiful illustration, is nearly always associated with the extracapsular fracture, and occurs under two varieties of form, the complete and the incomplete, of which the latter is by far the

Fig. 591.

Fig. 592.

Impacted Fracture of the Neck of the Femur.
Impacted Fracture through the Trochanter, the Upper Fragment being Wedged into the Lower.

more frequent. Old persons only are subject to it, and it is most common in those in whom the neck of the femur is of inordinate volume from the expansion of its spongy structure. The line of fracture is generally at the base of the neck, or at the junction of the neck with the shaft, the penetration occurring in the direction of the anterior surface of the bone, with which the neck is more immediately continuous, being separated from it behind by a well-marked depression, and by the large ridge connecting the two trochanters. The fracture usually happens from the body being crushed by the falling of a heavy substance upon the trunk, while the chest is inclined forwards, and the knee rests upon a solid surface, the hip at the same time receiving a severe blow, as when a person is buried by the caving in of a coal-bank ; or, it may be produced by a fall from a height upon the knee, in which the weight of the body is violently impelled in the opposite direction, the two forces continuing to act after the bony tissues have given way. The direction of the fracture is generally oblique, extending from above downwards from the great to the small trochanter, both of which are not unfrequently included in the injury, as in fig. 592.

The distance at which the upper fragment is buried in the lower varies from a few lines to half an inch, three-quarters of an inch, or even an inch, depending upon the degree of the impelling force and the amount of expansion of the cancellated structure at the base of the cervix. The compact substance of both fragments is often extensively comminuted, and the fragments themselves are usually interlocked in such a manner as to give the thigh-bone the appearance of being twisted upon its axis, the limb after the accident being generally everted, as in fracture without impaction, although in a less marked degree.

In this form of impacted fracture, Professor Bigelow is of opinion that, in the large majority of cases, the thin, friable posterior wall of the neck of the bone alone is driven into the trochanter, while the thick anterior wall remains free, its dense and more resisting structure refusing to yield except as a kind of hinge upon which the shaft rotates at the moment of the accident. To this circumstance may be ascribed the eversion of the foot, while the shortening is generally due to the obliquity of its hinge, which follows the anterior intertrochanteric line.

There is a variety of impacted fracture of the neck of the femur in which the lower fragment is impelled into the reticulated structure of the upper. The occurrence is uncommon, and the amount of shortening is a good deal less than in the more ordinary form of injury.

The *symptoms* of impacted fracture of the neck of the femur are generally very characteristic, although a good deal of care is necessary, in every case, in order to make a correct diagnosis. The most valuable and reliable phenomena are, the shortening of the thigh, the eversion of the foot, the ability of the patient to walk or to bear the weight of the body upon the thigh, after the accident, and the resistance which the fragments offer to extension and counterextension when an attempt is made to restore the limb to its natural position. The pain is usually very intense, generally much more so than in ordinary cervical fracture, and there is not unfrequently extensive ecchymosis over the great trochanter, causing unwonted swelling and discoloration. Crepitation can only be elicited by unlocking the ends of the fragments.

The degree of shortening varies, as already stated, from a few lines to an inch or more, the average ranging from a quarter of an inch to half an inch, which it rarely exceeds. The eversion of the foot, although well marked, generally exists in a slighter degree than in fracture of the neck of the bone without penetration, whether the injury is seated on the outside or within the capsular ligament. The occurrence is the more valuable as a diagnostic from the fact that it is rarely, if ever, entirely absent. As the continuity of the femur is preserved, the patient is generally able to walk after the accident, although not without much suffering, or, at all events, he can bear the weight of his body upon the affected member. For the same reason, the limb is easily rotated upon its axis, bent upon the pelvis, extended, abducted, or adducted ; and when an attempt is made to restore it to its normal length, the effort, unless very powerful, ordinarily fails, the ends of the fragments retaining their interlocked position, despite the extension and counterextension. Finally, there is generally, in addition to the symptoms now described, more or less deformity, although this cannot always be easily detected on account of the excessive swelling, and, when present, is not, of course, characteristic.

What, then, are the most important phenomena in a diagnostic point of view ? Beyond all doubt, the shortening of the thigh, the immobility of the limb, the existence of deformity at the hip, in the situation of the great trochanter, and the absence of crepitation. When

these signs are present, it may be assumed that there is no dislocation of the ilio-femoral joint, nor any ordinary fracture of the neck of the femur, but fracture of this portion of the bone with impaction of the uppper fragment.

The *prognosis* of this variety of fracture is much more favorable, so far as it respects reunion, than that of ordinary fracture of the cervix ; for, inasmuch as the fragments are firmly wedged together, it usually requires but little callus to effect their consolidation. Besides, very little retentive apparatus is usually necessary, the two fragments serving as their own splints. On the other hand, however, there must always remain a certain degree of deformity, consisting of slight shortening of the limb, and of an incurvated state of the thigh just below the hip. Some permanent lameness may, therefore, reasonably be looked for after the accident, even under the most favorable circumstances. I have seen several specimens of impacted fracture of the neck of the femur where great and irremediable ankylosis was produced by osseous matter being extended, in the form of bridges, from the seat of injury to the innominate bone, immediately around the acetabulum, connecting the two together in a solid mass.

These protective means are displayed in a remarkable manner in a specimen, above depicted, of impacted fracture of the neck of the left femur, in the Mütter collection. The head and neck of the bone, being nearly two inches and three-quarters in length, occupy a horizontal position in regard to the shaft, the neck being driven into the cancellated structure of the latter some distance below the trochanters. The superior third, or more, of the shaft is bent strongly forwards and outwards, and is surrounded by a casing of new osseous matter, more than half an inch in thickness at the concavity of the curve, or weakest portion of the femur, and at a point, consequently, where, after such an accident, the greatest amount of support is required. A large ledge of bone, two inches long, and very broad, thick, and firm, projects from the anterior and inner aspect of the superior extremity over towards the hip-joint, being connected by a strong, round ligament, upwards of two inches in length, with the anterior inferior spinous process of the ilium, which juts out as a remarkably long, slender prominence, more than twice the normal size. An idea of the amount of shortening of the femur may be formed, when it is stated that the summit of the great trochanter projected fully one inch above the upper border of the acetabulum. Nothing is known of the history of the case ; but, judging from the completeness of the reparation, the accident must have occurred many years before death. Some degree of motion, certainly very slight, must have existed both in the acetabulum and at the junction of the two fragments, the upper end of the lower of which was converted into a socket into which the lower end of the upper was received, a kind of adventitious membrane having been interposed between the contiguous surfaces.

In the treatment of this fracture, one important point is not to pull the ends of the broken bone asunder in the examination of the case. Hence, whenever impaction is suspected, the rule is to refrain from all rotation and extension. As soon as the nature of the accident is detected, the limb is placed in an easy position in bed, a pillow lying under the ham, and gentle but steady pressure is made, by means of a compress and bandage, in the direction of the great trochanter, with a view of rectifying any deformity that may exist in that situation. Generally, no splint will be required, but sand bags may be useful ; and in ordinary cases the patient will be able to move about on crutches in three or four weeks.

General Diagnosis.—Fractures of the neck of the thigh-bone are liable to be mistaken for other lesions, and it is, therefore, a matter of great importance to have accurate conceptions of their real nature, errors of diagnosis here being always particularly prejudicial both to the patient and to the practitioner. The affections with which they are most apt to be confounded are sprains and dislocations of the hip-joint ; and, in many cases, great difficulty is also experienced in deciding whether the injury is one of fracture within the capsular ligament, or of fracture exterior to it.

The symptoms of fracture of the neck of the femur, especially the intracapsular, are sometimes closely simulated by sprains and contusions of the hip, causing involuntary obliquity of the pelvis, with apparent shortening of the limb, and eversion of the knee and foot, along with excessive pain and difficulty of motion. The resemblance is occasionally so perplexing as to create doubt in the mind of the most skilful diagnostician, and, among the less informed, has often led to the most serious errors of practice, by the employment of harsh means when the most mild and soothing alone were necessary. The signs of distinction are the following :—1. In fracture the shortening is real, and can be effaced only by extension and counterextension ; in sprains and contusions, on the contrary, it is not real, but feigned, as may be proved by placing the limbs parallel with each other, and

bringing the two iliac crests on the same level. 2. In fracture the eversion of the foot is complete, the extremity presenting an appearance characteristic of total loss of power ; in ordinary injuries of the hip and upper part of the thigh the eversion is comparatively slight, and the patient can generally rectify it by his own efforts, although they may be productive of severe distress. 3. In fracture there is usually complete abolition of muscular action ; so that the thigh can neither be flexed, extended, nor rotated, however determined the attempt. It is only in the impacted fracture that the individual has still some control over the limb, and then the best guide for avoiding mistake is the existence of actual shortening. In sprains and contusions motion is diminished, perhaps very greatly, but not abolished.

A very unpleasant consequence of sprains and contusions of the hip-joint is shortening of the thigh from interstitial absorption of the neck of the femur. Hence the patient, on recovering from the immediate effects of the injury, finding that the limb is permanently disabled, might accuse his attendant of ignorance. In order to guard against such a charge, it is well for the surgeon to inform the patient, at an early period of the treatment, of the possibility of such a contingency.

It might be supposed, at first sight, that it would be very difficult, even for an inexperienced practitioner, to mistake a fracture of the neck of the thigh-bone for a dislocation of its head upon the dorsal surface of the ilium, yet numerous cases are upon record testifying not only to the possibility of such an accident, but to its actual occurrence in the hands of the most distinguished surgeons. The only way to avoid error is to remember clearly the most prominent signs of each lesion. The subjoined tabular arrangement will serve to place the subject in its proper light, at the same time that it renders a comparison of these symptoms an easy task :—

Intracapsular Fracture.	Iliac Dislocation.
1. Occurs nearly always in old persons.	1. Is most common in adult and middle life.
2. Is most common in women.	2. Occurs with equal frequency in both sexes.
3. Usually the result of slight causes.	3. Always produced by severe force.
4. The foot is strongly everted.	4. The foot is inverted.
5. There is great shortening, readily effaceable by extension and counterextension, but recurring the moment the force is discontinued.	5. The shortening is also great, and can be effaced only by restoring the bone to its natural position, when it will not return.
6. Marked crepitation exists.	6. There is no crepitation.
7. There is preternatural mobility, the ends of the fragments being movable upon each other.	7. The bone is in a fixed and constrained position.

But the greatest difficulty in the diagnosis of these affections of the thigh and hip arises from the embarrassment which the surgeon experiences in determining whether the case is one of intracapsular fracture, or fracture exterior to the capsular ligament. As the subject is one of great practical consequence, it deserves to be studied with unusual care, and I shall, therefore, arrange the principal points in tabular form :—

Intracapsular Fracture.	Extracapsular Fracture.
1. The result commonly of slight injury, often indirect.	1. Usually caused by direct and severe injury.
2. The shortening, slight at first, generally not exceeding a third or half an inch, gradually increases to two inches and upwards.	2. The shortening is as great immediately after the accident as it is at any time afterwards, and its extent also is usually less than in the intracapsular fracture.
3. The crepitation is indistinct, and can only be fully elicited by extension and counterextension.	3. Crepitation is uncommonly distinct, being often loud and ringing, and is readily perceived on laying the hand on the trochanter and rotating the limb.
4. Function is much impaired, but often, at first, not wholly abolished.	4. The loss of power is complete, the limb lying in a helpless, paralyzed condition.
5. The great trochanter, on rotating the limb, moves, as it were, upon a pivot.	5. The great trochanter is often partially separated from the shaft of the bone, and then but imperfectly obeys the movements of the limb.
6. The pain is unreliable, both as it respects site and intensity, being generally most severe at the upper and inner part of the thigh, in the direction of the small trochanter.	6. The pain is usually very severe, especially on manipulation or motion, and seated more in the direction of the great trochanter.
7. There is generally little or no contusion, swelling, or discoloration.	7. Usually severe contusion, with considerable swelling, ecchymosis, and discoloration.

Nothing of any diagnostic value can be deduced from a consideration of the age at which these two fractures occur, since, as was previously stated, both are met with almost

exclusively after the fiftieth year, there being only a few well-authenticated cases on record of its occurrence prior to that period. The same is true in relation to sex, experience having shown that this exercises much less influence upon the production of these two varieties of fracture than was formerly imagined. I am inclined, from a careful study of the subject, to place more reliance, in this respect, upon the existence of severe external injury, as contusion, swelling, and ecchymosis, and upon the presence of shortening, than upon any other phenomena. In the intracapsular fracture, the external signs of injury are, certainly, as a general rule, exceedingly slight, while the reverse is usually the case in the extracapsular, the parts being nearly always much bruised and discolored. In regard to shortening, it possesses, I think, great value as a diagnostic of the two lesions; for it may be assumed, on the one hand, that when it is very slight immediately after the receipt of the injury, and gradually increases afterwards, it depends upon intracapsular fracture; and, on the other, that when it is very considerable immediately after the accident, it is caused by extracapsular fracture. Rodet, who studied the subject with much attention, arrived at the conclusion that every fracture of the neck of the femur, produced by a fall or blow upon the great trochanter, was of an extracapsular nature; whereas every one occasioned by a fall upon the feet, or by muscular action, must be seated within the ligament. This conclusion, however, is altogether unfounded; in adopting it, we should be compelled to assume that all intracapsular fractures are the result of falls upon the feet, when all experience teaches that they are almost invariably produced by force applied directly to the hip.

The most important diagnostic characters of the impacted fracture of the neck of the femur, whether within or without the capsule, are, as has already been stated, shortening of the limb, the absence of crepitation, and the comparative or complete immobility of the fragments. The shortening is always immediate, and remains permanent in its original degree, unless the ends of the bone are rudely drawn asunder; hence it is a sign of an unequivocal character; the absence of crepitation is also very significant, and the trivial mobility, or complete absence of motion, is another circumstance of importance. The great danger in such a case is that the fracture may be mistaken for a dislocation; but from this it may usually be readily distinguished by a careful study of its history, and a thorough examination and comparison of the symptoms characteristic of the two lesions.

FRACTURES OF THE GREAT TROCHANTER.

Fracture of this bony apophysis may take place as an independent lesion, or as a concomitant of fracture of the neck of the femur, outside of the capsular ligament, as mentioned previously, and as exhibited in fig. 593, from a specimen in my collection. As an independent fracture, it is very infrequent in comparison with the other variety. It may occur at any period of life, but is chiefly observed in elderly subjects, as a consequence of direct violence, as a fall, blow, or kick, breaking off the trochanter in an oblique direction from above downwards. The fracture is sometimes comminuted, the trochanter being broken into several pieces, of irregular size and shape, the fragments grating under the fingers like so many pieces of china. It may also be compound, although, in general, it is unaccompanied by any wound of the soft parts.

Fig. 593.

Fracture of the Great Trochanter.

The *symptoms* of this fracture are generally well marked, the most important consisting of eversion of the limb, with separation of the fragments, inability to sit down, and difficulty of obtaining crepitation. The eversion is unusually distinct, and is probably due, at least in great degree, to the loss of power in the external rotator muscles; the limb lies in a helpless condition, and no effort that the patient can make can change its position. The broken trochanter is commonly widely separated from the shaft of the bone, and hence the difficulty which is generally experienced in eliciting crepitation, this being only practicable by placing the parts in apposition with each other. The displacement is either upwards towards the ilium, or downwards towards the tuberosity of the ischium, the former being the more frequent. If the patient attempt to sit down he is completely foiled, and immediately

experiences great increase of pain, compelling him to desist. Most authors speak of shortening of the limb as a symptom of this fracture, but, if shortening really exist, it can only be in a very slight degree. More or less contusion and ecchymosis of the soft parts are usually present.

The diagnostic signs are the eversion of the limb, the loss of prominence at the natural site of the trochanter, the fixed position of the small fragment on moving the shaft of the femur, and crepitation on approximation of the broken ends.

The union is by osseous matter, and, unless the bone is comminuted, a cure may reasonably be expected without any deformity of the hip or impairment of the functions of the limb. Considerable difficulty, however, is generally experienced in maintaining apposition of the fragments, and hence such an injury always requires more than ordinary vigilance on the part of the attendant.

The *treatment* consists in maintaining the limb in a perfect state of quietude by means of two long splints, the foot being supported in a perpendicular direction, with a slight tendency to eversion, which is the most natural position for a person when he lies on his back, and, therefore, the most eligible for relaxing the external rotator muscles when there is a fracture of the trochanter. The broken trochanter, being drawn into its natural situation, is confined there by a soft leather belt, long enough to extend around the pelvis, and furnished with a hollow pad, from three to four inches in diameter, for the purpose of embracing more effectually the prominence of the hip. Hardly any extension will be necessary. If the soft parts are much contused, leeches and fomentations should be applied before putting on the permanent dressings. After the patient has been confined for a month, he may be permitted to exercise on crutches. The annexed cut, fig. 594, represents an excellent mode of treating fractures of the great trochanter recommended by Sir Astley Cooper.

Fig. 594.
Sir Astley Cooper's Method of Treating Fractures of the Great Trochanter.

The great trochanter is occasionally detached from the neck and shaft of the femur, by the forcible laceration of the fibro-cartilage by which it is connected to these parts during early life, constituting what is known as the *epiphyseal* fracture, fig. 595, from Bryant. The union between these two parts is seldom completed before the twentieth year. The accident, which is very uncommon, is usually produced by a severe fall upon the hip, and is always extremely difficult of diagnosis, owing to the fact that there is seldom much, if any, appreciable displacement. In most of the recorded cases there was much diversity in the symptoms; in some the patient was able to walk immediately after the accident, while in others he had lost all control over the muscles of his limb; in some the foot was everted, while in others it preserved its natural position, or was even inverted; in all there was severe pain, with considerable swelling, either alone or conjoined with ecchymosis, at the site of injury, and, during their progress, more or less constitutional disturbance.

Fig. 595.

Epiphyseal Fracture of the Great Trochanter.

The best manner of determining the diagnosis, in this accident, is to make the patient lie on his back and incline the pelvis over the injured side, while the affected limb is thoroughly abducted, or carried away from the sound one. The gluteo-femoral muscles being thus completely relaxed, the trochanter, if detached, may easily be pushed into its natural position, and crepitation elicited by rubbing it against the neck and shaft of the femur.

The occurrence of this accident is not without danger, several cases having been recorded in which it proved fatal from extensive suppuration and constitutional disturbance.
When recovery takes place, the limb remains long weak and painful. The union, under such circumstances, is fibro-cartilaginous, or partly cartilaginous and partly osseous. The treatment must be conducted upon the same principles as in ordinary fracture of the trochanter. A very instructive case of this accident, in a lad sixteen years old, caused by a sprain, and eventuating in death from periostitis and pyemia, was reported in 1875, by Professor Roddick, of Montreal.

FRACTURES OF THE THIGH IN CHILDREN.

Fractures of the femur sometimes occur in very young children, and are always peculiarly troublesome. The bone generally gives way at its shaft, as the result of external violence, and the symptoms are characteristic. Diastasis of the femur is extremely uncommon. It is most frequently met with in the lower extremity of the bone; separation of the head is an occasional occurrence, and epiphyseal fracture of the great trochanter is also a possible accident at a very early age. In a case of diastasis of the head of the femur in a stout, fat, healthy girl, twelve years of age, the accident was produced by a fall on the hip, from a low hand wagon. The case was at first treated as one of dislocation. After the lapse of four months, during part of which the limb was kept in a state of rigid extension, there was shortening of scarcely half an inch, and the thigh could be moved in every direction. Unfortunately there are no symptoms by which diastasis of the head of this bone can be distinguished from ordinary fracture of the neck.

Fractures of the thigh-bone are much more frequent in children than is generally supposed. Coulon states that in one year 140 cases were admitted into the St. Eugenia Hospital at Paris. Of these, 26 affected the femur. This bone is occasionally broken during delivery. The youngest case that I have ever met with was an infant four weeks old, in whom the accident was caused by a child rolling over its thigh as it lay in bed.

The obliquity in fractures of the thigh in children is generally considerably less than in adults, and cases are met with in which they are nearly transverse. Hence the tendency to overlap is usually comparatively slight, although in some cases it amounts to several inches. A species of green-stick fracture is occasionally witnessed, similar to that of the bones of the forearm.

In infants at the breast the treatment of this class of injuries is always attended with peculiar embarrassment and annoyance, owing, first, to the remarkable tendency to displacement of the fragments, and, secondly, to the constant liability of the dressings to be soiled by the discharges. To meet the first of these contingencies, the limb, after the subsidence of the inflammation and swelling, should be enveloped in a plaster of Paris bandage, and incased in two very light splints, either of wood, gutta-percha, or binder's board, the outer one reaching from a short distance below the level of the foot to the crest of the ilium or even to the chest. Layers of wadding should be applied to ward off pressure, when the splints should be secured with adhesive plaster, and covered with a roller. A little additional support is generally necessary in front of the thigh. Soiling of the dressings is best obviated by a thick coating of gum-shellac, paraffin, or coachmaker's varnish, frequently renewed. The object of the long splint is to keep up a certain degree of extension, and to prevent the child from flexing the pelvis upon the thigh. It is very important that the limb should be frequently examined, otherwise it may become shortened and crooked. The consolidation will be completed in from fifteen to twenty days.

In children from five to ten years old I have usually found the most convenient and suitable apparatus to be a case made of stout, unoiled sole leather, long enough to extend from the groin to an inch and a half below the heel, and sufficiently wide to come well around the limb, especially the thigh. It is supplied with a foot-piece of the same material, and is well padded at its upper extremity, to prevent undue pressure upon the perineum. The outside portion of the trough is continued for some distance over the hip, to which it is secured by a spica, or common roller, carried around the thighs and pelvis. A splint, also of leather, binder's board, gutta-percha, thin wood, or plaster of Paris, is stretched along the forepart of the limb from the groin to the patella, wadding being suitably interposed to ward off pressure; the apparatus is held in place by means of an ordinary bandage, adhesive strips having previously been secured to the leg and attached to the foot-piece. The dressing is completed by placing the limb, with its apparatus, in an easy position upon a hair or cotton bolster, gradually tapering upwards, its thickness below not exceeding four inches. By this simple contrivance I have always found it easy to obtain the requisite extension and counterextension, the

perineum affording a point d'appui which effectually prevents the ascent of the apparatus, while the foot-piece serves to keep the foot in place, at the same time that it receives the extending bands.

When the patient is very restive, it may be necessary to employ long splints, connected below by a cross-piece crutched-shaped above, and provided with a foot-board, stretched along each side of the body, to which, as well as to each limb, they are attached by appropriate belts or straps, so as to render the lower extremities perfectly immovable.   The belt that passes around the pelvis must have an opening in it for the easy evacuation of the bowels.   The plaster dressing, if properly applied, may be very serviceable in the treatment of fractures of children, notwithstanding what has been said to the contrary.   A splint made of this material, and closely fitted to the limb, forms an excellent support in fractures of the femur, when there is little or no tendency to displacement. Even when this tendency exists in a marked degree, the necessary extension can generally be readily made with the aid of such an apparatus, provided it be prolonged a few inches below the level of the sole of the foot, the adhesive strips being attached to the sides of the splint.

In diastasis of the head of the bone, osseous union should, I think, always be looked for, if the case be judiciously managed.   One important element in the treatment of such an injury obviously is compression, by suitable apparatus, of the hip, the more effectually to prevent displacement.   The extension should be steadily maintained for at least six weeks, and the trunk kept as quietly as possible.   Passive motion should not be instituted under two months.

CHAPTER IX.

DISEASES AND INJURIES OF THE JOINTS.

SECT. I.—WOUNDS.

The joints are liable to be laid open in various ways—by cuts, stabs, punctures, balls, machinery, and other means—and hence such lesions are said to be incised, punctured, gunshot, contused, or lacerated, according to the nature of the vulnerating body.   In extent they may be small or large; in character, simple or complicated; in effect, trivial or severe.

The symptoms are generally sufficiently distinct.   When any of the large joints are opened, whether by a cut, laceration, or bullet, the nature of the accident is ordinarily denoted by an immediate escape of synovial fluid, rapidly followed by great pain, tension, and swelling of the part, with severe constitutional disturbance.   When the wound is very large, especially if it is of a gunshot nature, there will generally be, along with these symptoms, violent shock, the patient being deadly pale, faint, sick at the stomach, and slow in reaction.   In from twelve to twenty-four hours after the accident, fever commonly sets in, often preceded by rigors, and soon succeeded by delirium, great gastric distress, intense thirst, and excessive restlessness, with a strong, full, bounding pulse.   The local phenomena assume a more aggravated character.   The heat, pain, redness, and swelling increase in intensity; the surface of the limb, at the seat of the injury, often assumes an erysipelatous aspect, sometimes as early as the first twenty-four hours after the accident, and the discharge of synovial fluid steadily augments in quantity, as well as in consistence, exhibiting a thick, ropy, turbid appearance; or, if the wound is closed, and the fluid is retained, the joint becomes distended in every direction, but particularly in its more dilatable parts, the skin pits on pressure, and distinct fluctuation is perceived. The secretion now takes on a puriform character; the patient has frequent rigors, alternating with flushes of heat, and followed by copious sweats; the joint is exceedingly tense; the synovial membrane is universally involved; perforative ulcers form at different points; matter, often of a highly fetid nature, is freely discharged; the bones are rendered carious; and the ligaments, softened and thickened, yield at various points of their extent. In many cases matter forms exterior to the joint, and is extensively diffused among the muscles and through the subcutaneous connective tissue.

But it is not always that the affection progresses in this rapid and untoward manner.

In many instances, depending mainly upon the nature and extent of the lesion, and the character of the treatment, the inflammation, after having persisted for a few days, gradually disappears, and the patient recovers with hardly an unpleasant symptom, the joint, it is true, remaining temporarily stiff, but ultimately completely regaining its functions.

All lesions of this kind, however, should be regarded with suspicion; for, if they are not dangerous in the first instance, they are exceedingly liable to become so during their progress, and this is true of the most trivial wound as well as the most extensive. Sometimes a fortunate recovery occurs in cases, apparently, of the most desperate character. Thus, I attended a lad, fourteen years of age, who, while bathing, struck his knee against the sharp point of a rock, causing a severe penetrating wound, which healed without any serious local or constitutional symptoms, although it was at first in all respects most unpromising. In another instance, the knee-joint was opened by a pistol ball, entering by the side of the patella, and permanently lodging in one of the condyles of the femur, with no other effect than that of a moderate synovitis, and slight lameness.

Simple incised wounds are generally less to be dreaded than lacerated and gunshot, although undoubtedly many cases occur where the symptoms are extremely severe, and where the risk to limb and life is very great. It may also be assumed that wounds of a small joint are less dangerous than similar injuries of a large joint, incised than lacerated, small than large, and simple than complicated; the lesions, in these respects, being governed by the same laws as wounds in other parts of the body. There are several circumstances, however, which render wounds of the joints, especially the more important ones, as those of the knee, ankle, and elbow, peculiarly perilous, and which are the more to be dreaded because they are of frequent occurrence. These are erysipelas, pyemia, and tetanus.

Erysipelas, as a consequence of articular wounds, usually sets in within the first thirty-six hours, beginning at the site of injury, and spreading thence gradually over the neighboring surface. Its precise type will depend materially upon the state of the system at the time of the accident; its symptoms exhibit nothing peculiar, but its progress is often very rapid, and its presence is always denotive of a bad state of the constitution, which it is frequently difficult to counteract by remedies.

Pyemia and septicemia are frequent results of wounds of the larger joints, especially when of a lacerated, contused, or gunshot nature. Abscesses of the internal organs, as a consequence of pyemia, were occasionally noticed by some of the older surgeons. The viscera which are most liable to suffer are the lungs, liver, spleen, and kidneys, the disease usually appearing within the first five or six days, and speedily undermining the constitution. Large accumulations of pus occasionally take place in various parts of the connective tissue and in the splanchnic cavities, particularly the thoracic. As a concomitant of this occurrence, important changes take place in the local symptoms. The pain becomes extremely intense, the swelling rapidly increases, and the wound discharges an abundant fluid, of a thin, sanious, and highly fetid character, denotive of the bad nature of the inflammation. The general phenomena are typhoid, the patient is delirious, and death soon closes the scene.

Tetanus is an occasional occurrence after injuries of this kind, but not so frequent a one, perhaps, as is generally supposed. It usually comes on within the first week after the accident, and often terminates fatally in three or four days, few persons recovering from its effects. The occurrence is much more common in military than in civil practice.

The hemorrhage attendant upon wounds of the joints, although generally trivial, is occasionally very profuse, not always so much from lesion of the articular vessels themselves as from injury sustained by those in the immediate vicinity. When from any cause the blood accumulates in the articulation, it will be very apt to act as an extraneous substance, undergoing decomposition, and thus greatly aggravating the case.

Although injuries of this kind are generally attended with an escape of synovial fluid, there are cases, as when the wound is very long and narrow or valvular in its shape, in which there is no such appearance. Moreover, it must not be forgotten that in fat subjects wounds over a joint may furnish a fluid which closely resembles the synovial, but differs from it in being destitute of the oleaginous feel, which distinguishes the latter when rubbed between the fingers.

Treatment.—The treatment of these wounds is sufficiently simple, inasmuch as it involves no principles different from those which guide the surgeon in the management of similar lesions in other regions of the body. It consists, mainly, in removing extraneous

matter, approximating the edges of the incision, excluding the admission of air, forbidding all motion of the joint, and employing antiphlogistics to their fullest extent.

In a simple incised wound, a few strips of adhesive plaster generally suffice to effect approximation, and the risk of admitting air will be greatly diminished, if the part be covered with a compress wet with blood, and bound down by a roller, extending from the distal portion of the limb. Collodion, applied upon strips of patent lint, often makes an excellent dressing. If the wound is large, a few sutures may be necessary, carried, of course, merely through the common integument. When the wound is very ragged, the edges should be carefully pared, to place them in a better condition for immediate reunion. No air must be allowed to enter the joint, lest it cause decomposition of the inflammatory products.

When the wound is large, the synovial membrane may be covered with extraneous matter, as dirt, sand, or other substance, which may not only prove difficult of removal, but will be sure to enhance the danger of erysipelas, pyæmia, and tetanus. Clearance must be thorough, and the finger and forceps will be the best instruments for effecting it. Any clotted blood that may exist must be similarly dealt with. If the foreign matter is deeply imbedded in the joint, and the wound is disproportionately small, rendering a search for it difficult and uncertain, the safest plan will be to let it alone. Balls ought certainly always to be treated in this manner. If, on the contrary, the projectile lie loose in the articulation, it should unquestionably be extracted at once, and so with every other movable or floating body, provided it is readily accessible, or that it can be taken away without the risk of inflicting serious additional injury. All officious interference, by finger, probe, or other instruments, must be scrupulously avoided, as the synovial membrane is exceedingly intolerant and resentful of manipulation, however gently conducted.

Needles imbedded in a joint should be extracted without delay, and at all hazard, otherwise the most serious effects, as violent inflammation, suppuration, and ankylosis, will be sure to arise. The proper plan is to make a sufficiently large incision to obtain ready access to the foreign body without the risk of bruising and irritating the soft structures, the wound being immediately made air-tight by suture and collodion, and the limb placed upon a suitable splint, with the muscles in an easy, relaxed position. Morphia and quinine should be freely administered, and the joint enveloped in pounded ice, to prevent undue reaction.

When there is no prospect of union by the first intention, or when the condition of the wounded joint is such as to render suppuration inevitable, the proper plan is to draw the edges of the gap lightly together with adhesive strips, and to employ at once medicated applications, as lotions of acetate of lead and opium, or emollient cataplasms.

The joint is maintained in an easy, elevated, and relaxed position, all motion being guarded against by the use of splints and other suitable means. If the inflammation run high, and the patient is young and plethoric, blood is drawn from the arm, or, at all events, by leeches from the affected parts, the bowels are thoroughly moved, and the heart's action is controlled by depressants. Morphia, in large quantity, will be required to relieve pain and spasm ; and there is hardly a case, certainly no severe one, where it will not be proper to combine calomel with the anodyne, with a view to its speedy effects upon the system. The acknowledged efficacy of mercury in all inflammations of the serous textures clearly points to its administration as a matter of paramount importance here. It not only exerts a most happy influence upon the capillary vessels of the diseased membrane, modifying and changing their action, but it is a powerful sorbefacient, causing the removal of effused fluids. Its effects, however, must be carefully watched, lest they exceed our intention, which is only to cause tenderness of the gums, not positive ptyalism. Along with these general measures, local remedies must be used, of which the most trustworthy are evaporating lotions, the early and energetic use of ice, and intermittent, digital compression of the main artery of the limb.

During the progress of the treatment, matter may form within the joint, and become pent up for the want of an adequate outlet. Under such circumstances, relief must be afforded by a valve-like aperture, the puncture being immediately closed by collodion, and afterwards reopened as occasion may demand. When the quantity of pus is very great, pressing upon the joint in every direction, a free, direct incision should be made to admit of full drainage. It has always appeared to me that surgeons are too timid in these cases, and that they do not sufficiently coöperate with nature in her efforts at relief. It is not necessary here to describe the pernicious consequences which purulent accumulations, especially if long retained, must inevitably exert upon the component elements of the articulation. They can be nothing short of utter ruin of the synovial membrane, car-

tilage, and bone. Early evacuation must also be effected, if matter form immediately around the joint, beneath the skin, and among the muscles.

When the discharge is profuse and offensive, injections of infusion of linseed, slightly medicated with the chlorides, will be of service; they should be thrown in tepid, several times in the twenty-four hours, and may occasionally be advantageously followed by the introduction of very weak solutions of iodine, or of nitrate of silver, with a view of modifying the action of the synovial membrane. Too much caution, however, cannot be used in the application of these remedies, as the inflamed membrane is often exquisitely sensitive, and intolerant of such interference.

Whenever there is extensive suppuration, the parts will either recover by ankylosis, or the cartilage and bone will become so involved in the disease as to require removal. In the former case, the joint should be placed in the best position for future convenience and usefulness; while in the latter the affected structures should either be excised, or the limb amputated. The choice of the operation must be regulated by circumstances. If the inflammation has measurably subsided, and the patient's strength is not too much exhausted, the joint may possibly bear excision; in all cases of an opposite character, removal of the limb will be the safer operation.

In the milder forms of wounds, unattended with risk to limb or life, the great point is to guard against ankylosis, which is so liable to occur even in the most trivial affections of the articulations. Passive motion, sorbefacient embrocations, and the gradual use of the limb, will be the surest means of success.

Primary amputation will be required when the joint is severely shattered, whether by gunshot or otherwise, and the external opening is unusually large, or complicated with lesion of the principal vessels and nerves of the limb. It may be assumed, as a rule, that gunshot wounds of the large articulations of the extremities are nearly always fatal if amputation is not speedily employed. The same is true, although in a more limited sense, of gunshot injuries of the joints of the toes and fingers, in which tetanus and other bad effects are prone to ensue. When, as occasionally happens, the articular surfaces are covered with foreign matter, which it is impossible to detach without injury to the synovial membrane, the safest plan will be to amputate the limb. Conservative surgery in such a case is decidedly bad surgery.

SECT. II.—CONCUSSION.

The joints, like other parts of the body, are liable to concussion, the effect of the forcible contact of their surfaces; and such accidents may occur in various degrees, from the slightest disturbance to the most violent commotion. Blows and falls, operating either directly upon the part or indirectly through some intermediate structure, are the most common causes of the occurrence. The force inflicting the injury is generally transmitted, as is exemplified when a person falls from a great height and alights upon his feet, where the force, instead of being expended upon the parts struck, is sent along the leg to the knee, and thence through the thigh to the hip, the latter, perhaps, receiving the main brunt of the blow. When the concussion is very severe, the joint may be more or less contused, and it may even be attended with fracture of the articular extremities of the bones. In such an accident, shock is conjoined with contre-coup. The joint, instead of transmitting the shock, is severely concussed, the force being concentrated upon its anatomical elements, the adjoining structures escaping with but little injury, although there may occasionally be slight laceration of some of the ligaments. The effect may be limited to one joint, or it may involve several, as when a person falls from a considerable height and alights upon his feet or knees. In this way excessive shock of the spinal column is often produced, every joint being violently shaken, at the same time that more or less of the force is transmitted to the spinal cord, its envelops and nerves, causing an amount of injury which, if not immediately fatal, is often followed by the most serious consequences. Concussion of a joint is occasionally produced by very slight causes. Thus, I have been several times consulted on account of severe pain and lameness of the fingers, produced by striking the keys of the piano; and there are few persons who have not experienced a similar effect in the toes, from knocking their extremities forcibly against a stone or some other hard, resisting body.

When a large joint is severely concussed, the symptoms will be those of ordinary shock, and some time may, therefore, elapse before the patient recovers from the immediate effects of the injury. In many cases, indeed, the parts continue to be weak, tender, and stiff for an indefinite period, if not during the remainder of life. A very singular, if not

unique, case of this kind, occurring in the hip-joint, was recently reported by Dr. W. H. Daly, of Pittsburgh, and affords a beautiful illustration of the nature of this class of affections. A very strong, muscular man, twenty-three years of age, in the act of jumping suddenly out of bed, while the foot was forcibly abducted, and the whole weight of the body thrown upon the corresponding side of the pelvis, tore away the round ligament from its acetabular attachments, and violently contused the head of the femur at its postero-superior circumference over a space of two inches in length by one inch in width. No signs of fracture or of dislocation existed, and, what was very remarkable, the man walked four miles the day after the accident, although not without severe pain. Violent inflammation ensued, followed by death from tetanus at the end of thirty-six days. The structures around the joint were greatly softened and infiltrated with bloody serum, while the articular cartilages at the points of injury were disintegrated, pulpified, and partially removed by ulcerative absorption. No pus was found, and the capsular ligament was intact. In subjects predisposed to scrofulous disease, a bad form of synovitis is apt to arise, followed eventually, if the parts do not receive proper attention, by complete disorganization of the injured joint. In gouty and rheumatic persons, a slow, chronic inflammation is not unfrequently set up, causing severe pain and difficulty of locomotion, and leading to serious alteration of structure, as ivory degeneration of the bones and cartilages and the development of exostoses around the articulation.

The *treatment* of this class of injuries is sufficiently obvious. The great point is to keep the parts perfectly at rest, in an immovable position, insured, if necessary, by appropriate splints. For the first few days the affected joint should be wrapped up in cloths wet with a strong solution of acetate of lead and opium ; or, if the injury has been unusually severe, surrounded with a bladder partially filled with pounded ice. Leeches may be required when there is danger of active inflammation. Anodynes are given to allay pain and spasm. After the primary effects of the injury have passed off, passive motion is instituted, the hot and cold douches applied, and free use made of liniments and embrocations, along with gentle exercise, care being taken for some time not to bear much weight upon the affected structures.

SECT. III.—SPRAINS.

A sprain is the wrenching of a joint in which its ligaments are severely stretched, if not partially torn, and more or less injury is done to the parts around. Falls, blows, and twists, attended with rotation of the articulating surfaces, or a movement of these surfaces in opposite directions, are the most common causes of the accident.

The joints most liable to sprains are the ginglymoid, or those which admit of motion principally in two directions, as the knee, ankle, and elbow. The articulations of the toes, thumb, and fingers frequently suffer for the same reason, their functions and exposed situation rendering them especially prone to such accidents. The reason why the orbicular joints are so seldom affected in this way is their greater latitude and freedom of motion, their surfaces being thus enabled to undergo extensive rotation without putting their ligaments or the surrounding parts materially upon the stretch, whereas in the hinge-like joints the most trivial twist, by opposing a sudden check to their extremities, must necessarily cause a severe wrench. Moreover, it must not be forgotten that there is an essential difference in the structure of the ligaments themselves in the two classes of joints, which cannot fail to exert a powerful influence upon the production of the accident in question. In the orbicular joints the connecting media are of a fibrous texture, comparatively thin, yielding, and extensible, and, therefore, able, to a considerable extent, to get out of the way of injury ; in the ginglymoid, on the contrary, the ligaments are exceedingly firm, short, and indisposed to stretch, or, when stretched, incapable of withstanding rupture of their fibres. The orbicular joints are, however, notwithstanding their greater latitude of motion and the more yielding nature of their ligaments, occasionally severely sprained in consequence of the extreme abduction of the limbs. Thus the ilio-femoral articulation is sometimes violently sprained by the sudden slipping of the foot outwards, far beyond the line of the body, so as to put both the capsular and round ligaments strongly upon the stretch, inducing symptoms extremely simulative of dislocation of the head of the bone into the thyroid notch.

It is probable that there is, in every case of severe sprain, more or less injury inflicted upon the parts in immediate relation with the affected joint. The muscles and tendons must necessarily participate in the wrench, sustaining partial displacement, and sometimes even slight laceration ; the nerves and vessels are stretched, and the skin is often bruised

and discolored, especially when the accident has been the result of external violence. In the latter case, the articulating surfaces, being violently brought together, not only experience severe shock, but a considerable degree of contusion, thus greatly aggravating the suffering. Now and then, indeed, small portions of cartilage, or even of bone, are chipped off or partially displaced, but still slightly adherent to the sprained ligament, constituting what is known as the *sprain-fracture*, particularly common in the ankle-joint.

The *symptoms* denotive of sprain are, the instantaneous occurrence of pain, referred to the affected joint, impairment, if not total loss, of motion, and a sense of faintness or sickness, caused by the shock of the system, which is sometimes extremely severe, even when no external injury has been sustained, the accident having been induced merely by a wrench or twist of the limb. If some time have elapsed since the accident, there will be swelling and tenderness of the integument, as well as of the deeper structures, and probably also an indistinct perception of crepitation, depending upon the deposit of plastic matter. Discoloration of the surface, from extravasation of blood, is also very common. The pain is often excessive, especially soon after the accident, and quite overpowering in its effects.

The only accidents with which a sprain is liable to be confounded are dislocation and fracture; from which, however, it may generally be readily distinguished by a careful manual examination, by the form of the joint, by a comparison of the length of the affected limb with that of the sound one, by the history of the cause of the lesion, and, lastly, by the fact that the patient is usually able to use the parts, at least to some extent, immediately after the receipt of the injury. In fracture the most reliable symptom is crepitation. The examination should always be most thorough, lest a luxation or fracture be ultimately found, perhaps when too late to effect reduction, where originally only a sprain was suspected.

When the sprain is slight, the pain gradually subsides, the swelling is resolved, and the joint soon regains its accustomed functions. It is far otherwise, however, when the injury is of an opposite character, or attended with severe wrenching of the ligaments, violent contusion of the articular surfaces, and considerable lesion of the surrounding parts. The suffering will then be proportionately great, inflammation will be apt to run high, convalescence will be tedious, and the joint may remain weak and tender for many months, if not for years. A severe sprain, in fact, is often a much more serious accident, as it respects its secondary effects, than a dislocation or a fracture near a joint. In neglected or ill-treated cases, and sometimes even when every possible precaution has been adopted, the articulation continues not only to be weak and uncomfortable for a long time, but the corresponding limb becomes cold, wasted, flabby, and exquisitely sensitive; perhaps also the seat of neuralgic pain, subject to severe exacerbation whenever exercise is attempted, or there is a change in the weather. Occasionally, indeed, the movements of the joint are permanently lost. Conjoined with this local trouble there is generally grave disorder of the general health, the patient being extremely nervous, irritable, and dyspeptic, fancying himself helpless and disqualified for all useful exertion, both of mind and body. The probable cause of all this suffering is the shock or concussion sustained by the nerves of the affected joint at the moment of the accident, the effect thus produced exercising a pernicious influence upon the nutritive functions of the whole limb, and indirectly upon the well-being of the general system, especially the great nervous and ganglionic centres.

Treatment.—The leading indications in every case of sprain, whether light or severe, are, first, to limit and combat inflammation, and, secondly, to restore the joint, if possible, to its wonted functions. The former is fulfilled by the judicious use of antiphlogistics; the latter, by sorbefacients, passive motion, and exercise in the open air.

As soon as the affected joint has been properly examined, the limb connected with it is carefully bandaged, and placed perfectly at rest in an easy, elevated, and relaxed position, splints, a wire case, or a wooden box being used, if necessary, to insure more certain quietude and support. Sometimes the object is readily attained by laying the limb simply upon a pillow, although in warm weather this will be objectionable, as tending to keep up too much heat. Fomentations will usually be found to be more agreeable and soothing than cold applications, especially during the first few days, in nervous, irritable subjects; and the one which I generally prefer is a strong solution of acetate of lead and opium in hot water, applied by means of a piece of flannel, arranged in three, four, or six layers, and covered with oiled silk, to confine the heat and moisture. Instead of removing the cloth whenever it becomes dry, the best plan is to squeeze the lotion upon it from a sponge, as this will obviate injurious motion and exposure to the atmosphere. Solutions of chloride

of ammonium and opium, a mixture of warm water, laudanum, and alcohol, and thin bags of hops, will also be found extremely soothing. Occasionally pounded ice, applied in a bladder, is more agreeable than any other local remedy, especially in young, plethoric subjects. In sprains of the ankle-joint, excellent effects frequently follow the protracted immersion of the limb in hot lye or hot salt water. When the pain and swelling are unusually severe, leeches will be necessary; and great benefit will then also accrue from the localized steam bath, applied twice a day for an hour at a time. Anodynes are given to allay muscular spasm. Purgatives must not be neglected; and constitutional excitement must be allayed in the usual manner. In short, the antiphlogistic system must be carried out in its fullest extent.

When warm applications disagree, or fail to give relief, they should be replaced by cold, consisting either simply of water, of ice, or of some refrigerating mixture. The proper rule, in all cases, is to continue no remedy longer than it is found to be soothing and beneficial. The bandage must be carefully watched; judiciously employed, its effects are usually highly advantageous, affording support to the injured joint and limb, preventing swelling and spasm, and promoting the absorption of effused fluids.

In the milder forms of sprains, more simple means will, of course, answer, such, for instance, as applications of the tincture of arnica, laudanum, or laudanum and spirit of camphor, together with perfect quietude of the affected parts. In cases of this description the immediate application of the immovable bandage affords almost instantaneous relief, and materially shortens the cure.

The urgent inflammatory symptoms having been thus dissipated, embrocations, liniments, or lotions will be of use, the object now being the removal of effused fluids and the gradual restoration of the functions of the joint. These should be applied at first once, and afterwards twice, a day with the bare hand, the friction being regularly increased as the pain and tenderness diminish, and it will be well generally to keep the parts wet with the medicine by means of a piece of flannel. Whatever local remedies be used, the bandage must on no account be neglected; for, beneficial as it may have been in the first instance, its effects will now be incomparably more so. The limb, weakened by the previous suffering, requires tone and support, and there is nothing so well adapted to promote this object as the careful and judicious employment of the roller. It should be renewed at least once a day. Sometimes the bandage may be advantageously replaced by adhesive strips, applied as in dressing indolent ulcers.

At a still later stage of the treatment, great benefit may be expected from the cold douche, the water being pumped upon the part, or poured from a considerable height, and the surface well rubbed afterwards with the bare hand, or a piece of coarse flannel. In some cases, where a more powerful impression is necessary, it will be found highly advantageous to precede the cold by the hot douche. Along with these means, the use of the bandage is still steadily continued, and it may even be necessary to persist in the employment of stimulating embrocations. In very obstinate cases I have occasionally derived marked benefit from the daily application of fish-brine, rubbed on well with the bare fingers. Sometimes a blister affords more relief than any other remedy, and now and then electricity is advantageous.

As soon as the disease has reached the chronic stage, the joint must be gently exercised, and the patient made to walk about upon crutches in the open air. As great care should always be taken, in the acute stage, not to move the parts too soon, so in this its employment must not be too long postponed. Motion is the proper stimulus of a joint, as air is of the lungs, or food of the stomach, and when, after any injury, it is long neglected, serious consequences will be sure to arise. By and by the crutch must be laid aside for the cane, and this in turn for the limb, the joint and muscles being gradually forced into action. In nervous, hysterical persons this will often be a sore trial, requiring no ordinary effort of the will; nevertheless, it must be done; there is no alternative; the parts must be used, or they will inevitably remain stiff and tender, and ultimately become worthless.

Massage is of great value sometimes even in cases of recent sprains, and when properly practised, is extremely beneficial, rapidly relieving pain and swelling, and promoting the restoration of the functions of the affected joint. It must, of course, not be employed too rudely at first, or repeated too frequently. One application a day, or even every other day, will be quite sufficient, if continued for fifteen to twenty minutes at a time.

When there is much constitutional suffering, as there often is in the more severe forms of sprains, alteratives and tonics will be needed, the most suitable being blue mass, quinine, iron, iodide of potassium, and bichloride of mercury. Exercise in the open air must not be neglected.

SECT. IV.—SYNOVITIS.

Inflammation of the joints, technically called synovitis, is liable to occur in all articulations, but more especially in the large and more important, and may be induced by various causes, both local and constitutional, as exposure to cold, the presence of interarticular bodies, and mechanical violence, as sprains, blows, falls, and contusions. In the great majority of cases, however, it arises from the effects of rheumatism, gout, eruptive fevers, syphilis, scrofula, and the inordinate use of mercury.

The *symptoms* characterizing inflammation of the synovial membrane are, stiffness of the corresponding joint, usually greatest in the morning immediately after rising, but gradually diminishing upon exercise ; pain and tenderness on moving and percussing the limb ; swelling and fluctuation of the affected part ; a pale, glossy appearance of the skin ; inability to maintain the extended position ; and a sense of heat within the articulation. As the disease progresses the symptoms increase in severity, and the system, sympathizing with the local disorder, is thrown into violent commotion, there being high fever, a full, bounding pulse, and an arid state of the skin, with excessive thirst, and all the other phenomena of inflammatory excitement. In this condition the pain is generally very excruciating, especially at some particular spot, depriving the patient completely of appetite and sleep, and requiring opiates in large doses for its relief.

The disease, however induced, frequently comes on in a slow, gradual, and insidious manner, even when caused by external injury, being characterized, perhaps, merely by a trifling enlargement of the joint, arising from an increase of synovial fluid within its cavity, or partly from this and partly from inflammatory deposits in the surrounding structures, attended with some degree of tenderness on pressure, and more or less suffering on motion of the affected parts. Eventually, however, yet it may not be under several weeks, or even months, the joint assumes a soft and really swollen appearance, as in fig. 596, the limb becomes wasted, the functions of the articulation are materially impaired, and all the symptoms are aggravated.

Fig. 596.

Acute Synovitis of the Right Knee.

In rheumatic synovitis the symptoms are usually bold and well marked from the start. The attack often comes on in the following manner. The patient, having been exposed to cold, or been guilty of some excess in eating or drinking, retires at night with some degree of soreness in his joints, commonly attended with a general feeling of uneasiness, and wakes up in the morning with excessive pain, great tenderness on pressure of the affected parts, with considerable discoloration of the surface, and, probably, utter inability to use his limb. He is feverish and uncomfortable ; his pulse is strong and full ; the skin is hot and dry ; the bowels are costive ; and the urine is scanty, high-colored, and loaded with urates. The joints become gradually more deeply involved ; all the local symptoms increase in violence ; an abundance of synovial fluid is effused ; and, if the inflammation is not speedily arrested, suppuration will probably take place, the event being preceded and accompanied by rigors and high constitutional excitement. The joints most liable to suffer from rheumatic synovitis are the knee, ankle, wrist, and elbow, those of the hip and shoulder being seldom involved. The articulations of the fingers also frequently suffer, and that of the great toe rarely escapes when the disease in the other joints is at all severe. The inflammation often begins simultaneously in several joints ; or, if it commence in one, it is extremely apt to involve others in its progress, especially its fellow of the opposite side. Thus, articular gout or rheumatism of one knee nearly always attacks the other knee before it finally ceases.

In chronic articular rheumatism, calculous concretions are liable to form, especially in the joints of the fingers, where they always prove a source of great inconvenience and suffering. Their character will be specially considered under the head of interarticular bodies.

Syphilitic synovitis belongs to the tertiary form of syphilitic disease, and seldom makes its appearance until several years after the primary affection. It is most frequently met with in persons whose health has become exhausted by profuse courses of mercury and habitual intemperance. The larger articulations, especially those of the knee and elbow, are its most common seat ; but the smaller ones, as those of the fingers,

are by no means exempt from it. A good deal of effusion of synovial fluid usually attends; the joint, in consequence, is swollen and fluctuating, motion is impeded, the parts are tender on pressure, and the patient is harassed by excessive pain, which is always worse at night, after he becomes warm in bed. This latter circumstance, together with the history of the case, and the coexistence of syphilis in other structures, will always suffice to determine the diagnosis.

Of strumous synovitis particular mention will be made under a separate head; meanwhile, it is only necessary to state that the disease is almost peculiar to childhood, that it most commonly attacks the hip, knee, or elbow, and that it occurs only in persons of a strumous predisposition.

Suppuration, as a consequence of ordinary synovitis, is unusual. Arthritic inflammation of the joints also rarely terminates in the formation of pus, and a similar remark is applicable to articular syphilis; in scrofulous affections of the joints, on the contrary, suppuration is extremely common, and constitutes one of the great dangers of the disease.

The phenomena which announce the formation of matter are usually unequivocal. After the disease has continued for some time, violent rigors set in, followed by high constitutional reaction and copious sweats, the patient being delirious, excessively restless, and tormented with thirst. All the local symptoms are greatly aggravated, as is shown by the severity of the pain, the rapid increase of the swelling, the extraordinary heat, and the deep discoloration of the skin. If the pus is not speedily evacuated, hectic irritation supervenes, the appetite declines, the sleep is interrupted, the surface is drenched with perspiration, colliquative diarrhœa sets in, and death gradually closes the scene. This, however, is not constantly the course pursued by the disease. In many cases ulceration takes place, and the matter, thus finding vent, ceases to commit further ravages, although generally not until the cartilaginous and osseous tissues have become deeply involved in the mischief, and the patient, consequently, is doomed to carry out a miserable existence, with a stiff joint and a deformed limb, or to perish from the remote effects of the disease, after many months, if, indeed, not several years, of great suffering.

A joint that has once been inflamed from any cause whatever, remains long weak, and predisposed to disease, the most trivial circumstance tending to induce relapse, and to reawaken the symptoms in all their primitive severity. A frequent repetition of the morbid action must necessarily, by degrees, lead to disorganization of the component structures of the joint and to more or less extensive adhesions between the contiguous surfaces, eventually followed by complete loss of function.

The *pathological* changes which characterize this affection must necessarily vary a good deal, according to the nature of the exciting cause, and the duration of the morbid action. In the earlier stages of the disease there ordinarily is merely some degree of vascularity, along with slight opacity of the affected membrane, and some increase of the natural secretion. Here and there a little plastic matter is perceptible, either adherent to the inflamed surface, or floating about in the midst of the synovial fluid, which is usually, at the same time, more or less turbid, and abnormally thick and viscid. At a subsequent period, and especially in the more severe forms of the disease, these morbid appearances exist in a still higher degree. There is a greater amount of lymph, the vascularity is more intense, as well as more diffused, and the synovial secretion is of a dirty, glutinous nature. In some instances pus is freely poured out, and lining membrane, cartilage, and bone are all involved in the ruinous consequences. In the worst cases, the purulent fluid, exciting perforative ulceration, escapes from the joint, the passages afterwards remaining fistulous. The surrounding structures are thickened by plastic deposits, softened, or softened at some points and indurated at others, and unnaturally red and congested.

Treatment.—When the disease is one of ordinary character, depending upon traumatic causes, or ordinary constitutional derangement, as a depraved condition of the secretions, or upon suppression of the cutaneous perspiration, it will generally be found to yield to the judicious application of the more common antiphlogistic measures, such as would be indicated in common inflammation of other parts of the body. If the symptoms are at all urgent, and the patient is young and robust, blood must be freely taken from the arm, and the bowels opened with an active cathartic, followed by antimonial and saline preparations, with the addition of a sufficiency of morphia to promote perspiration, allay pain, and induce sleep. Mercury is administered when there is danger of structural lesion, or evidence of plastic effusion, and is carried to the extent of rapid but gentle ptyalism, with the hope of saving texture and preventing adhesion. The diet is light and spare; the drink cooling and acidulated.

As it respects the local means, the joint is placed in an easy, elevated, and relaxed position, over a pillow or bolster, the limb being put up, if necessary, in splints, or other suitable apparatus, for the purpose of more certainly insuring quietude. The rest must be absolute and unconditional. If the affected surfaces are permitted to rub against each other, even in the slightest degree, the effect must inevitably be to aggravate and protract the morbid action.

Of direct topical applications the most important are leeches and fomentations. Leeches, however, are, as a general rule, only necessary in the more urgent cases, attended with great pain, heat, and swelling, and then they should be employed freely, in such numbers and in such a manner as the violence of the disease and the condition of the system may seem to indicate. Cupping is not to be thought of in inflamed joints, as the percussion attending the operation causes more injury than benefit. In young and otherwise healthy subjects, especially in hot weather, cold applications, medicated freely with laudanum, are sometimes exceedingly grateful and beneficial, promoting evaporation, allaying pain, and opposing swelling; but, in general, warmth combined with moisture will be found to be most soothing and agreeable. The best plan, however, always is to consult the feelings of the patient, or to change the applications whenever they cease to be beneficial. When these means fail, or when the disease is making rapid progress, there is no remedy so capable of affording relief as a blister, large enough to cover in the whole joint, well sprinkled with morphia, and retained until it has produced thorough vesication, the parts being dressed afterwards with a light, emollient poultice or with cloths wrung out of warm water, with a piece of oiled silk over the surface to confine heat and moisture. Cantharidal collodion is generally preferable, as a vesicant, to the common blister, as the latter is often adapted with difficulty to the shape of the affected joint.

If matter form, it is to be dealt with in the same manner as in other parts of the body. It is folly to look upon it in any other light. It is pent up, and, as it is not amenable to the action of the absorbents, it must be evacuated as early as possible, before it has caused any serious structural evil. The employment of the aspirator generally affords excellent results, except when the matter is unusually thick, when an incision must be made, not, of course, direct or large, but subcutaneous and small, the orifice being immediately closed to prevent the admission of air. A timid, cautious course does not answer here; so long as the pus is confined it must keep up pain, and injure the structures with which it lies in contact; impairing and ultimately destroying their vitality, and thus putting both limb and life in imminent peril. The opening should always be made at a dependent part, and be repeated from time to time until the matter ceases to accumulate, the joint being well supported in the interval by a bandage, or by a roller and adhesive strips. In some cases the joint may be so completely distended with pus as to demand imperatively a free direct incision for its relief; a course of treatment upon the importance of which I have strenuously insisted for more than a third of a century in my annual courses of lectures. When ulcerative perforation has taken place, free drainage must be established, and it is in such cases that the seton passed through the joint, as recommended by Sayre, may occasionally be advantageous. In any event, antiseptic dressings must be employed.

The surgeon need not always despair of effecting a good cure even after suppuration has taken place, if the above measures are cautiously carried out; the joint will probably be stiff, but it should be recollected that an ankylosed joint is always better than no joint at all, provided it is put in a proper position for future usefulness.

When the disease has passed into the chronic stage, the main reliance must be upon the steady, persistent use of the bandage, the douche, stimulating lotions, and friction. The joint is showered twice a day, first with hot, and immediately after with cold water, when, being dried, it is thoroughly rubbed with some embrocation, or mild mercurial ointment, or painted with a weak solution of iodine, and put up in a roller, extending from the distal portion of the limb. Passive motion is instituted, and steadily continued so as to make gentle and equable friction upon every part, until there is complete restoration of the functions of the joint. Gentle exercise must be taken upon crutches in the open air; and for a good while the limb must not be permitted to sustain the full weight of the body. In some cases the joint may be advantageously strapped with ammoniac and mercurial plaster, or a plaster composed of opium and galbanum, to promote the absorption of effused fluids, and lend support to the weakened structures. Compression with a wet sponge is also a most valuable remedy in such an event. If the case prove obstinate, the fluid may be removed by aspiration, and the joint be subsequently strapped,

when the remaining symptoms may be scattered by the use of iodide of potassium with a minute quantity of bichloride of mercury, given three times a day, and pushed to gentle ptyalism. When ankylosis is found to be unavoidable, all motion of the joint should be prohibited, and the limb placed in the position in which it is most desirable it should be in that event.

I have said nothing here of counterirritation by tartar emetic pustulation, vesication with croton oil, and the use of issues, the seton, and the moxa; because, although sometimes serviceable, these means seldom afford the relief that has been so generally ascribed to them. I have certainly not, in my own practice, found them of much advantage, while occasionally I have thought they had acted decidedly prejudicially. Pustulation with tartar emetic is not only extremely painful, but it not unfrequently, in delicate persons, creates nausea and other disagreeable effects, rendering its continuance improper. The use of croton oil is hardly less objectionable. An issue may sometimes be established beneficially directly over the affected joint with the actual cautery, or the hot iron may be drawn linearly over its surface at several points, in a vertical direction. The seton should never be used in any articular disease as a counterirritant.

In rheumatic and gouty affections of the joints the most reliable remedy is the wine of the seed of colchicum. Its efficacy will generally be greatly increased, especially in young, vigorous subjects, if its exhibition be preceded by an active purgative, and the loss of ten, fifteen, or twenty ounces of blood. The best plan is to give one drachm of the wine every evening at bedtime in union with one-third to half a grain of morphia, such a course being far preferable to smaller doses frequently repeated. Thus administered, it rapidly subdues morbid action, relieving pain, depurating the blood, and expelling or neutralizing the arthritic poison. When there is much arterial excitement, as evinced by a full, bounding, and frequent state of the pulse, the saturated tincture of aconite will come in play, from three to four drops being given every three, five, or six hours, either alone, or, what is usually better, in union with a minute quantity of antimony and the sixth of a grain of morphia, in order to produce a more powerful diaphoretic impression. In the use of these several articles, great caution is needful that the dose be not carried too far, or the remedy continued too long.

If, after proper depletion has been practised, the disease be found to be unusually rebellious, calomel and opium may be cautiously employed, with a view to gentle ptyalism. In this condition of the system, quinine will often be highly serviceable, especially if it be administered in large doses in combination with morphia or Dover's powder. The alkalies, especially the carbonate of sodium, taken in strong lemonade, are beneficial in neutralizing the acid state of the blood and in improving the tone of the stomach.

As a local application, nothing will be more beneficial than soap liniment with laudanum and aconite, well rubbed on twice a day, and retained constantly upon the affected joint with flannel, covered with oiled silk. This may be succeeded, if the disease be inclined to linger, by vesication with cantharidal collodion.

In syphilitic synovitis, the great remedy, as stated elsewhere, is iodide of potassium, conjoined, in obstinate cases, with mercury, carried to gentle ptyalism. Other means, both general and local, such as have already been adverted to, are not to be neglected.

SECT. V.—DROPSY OF THE JOINTS.

Dropsy is an accumulation of fluid in the interior of an articulation, generally a result of chronic disease of the synovial membrane. It is most common in the ginglymoid joints, as the knee, elbow, and ankle, especially the first, which suffers more frequently in this way than any other.

The causes are both local and constitutional. Among the former may be classed different kinds of accidents, as sprains, blows, concussion, dislocation, and the presence of interarticular concretions, irritating the synovial membrane, and inducing an inordinate secretory action in its vessels. Severe and long-continued exercise, attended with excessive fatigue of the joints, may also excite the disease.

The constitutional causes are not always very obvious. Very often the disease is associated with, or directly dependent upon, a rheumatic state of the system, as is clearly evinced by the consentaneous existence of rheumatic suffering in other parts of the body. Gout occasionally produces a similar effect. In tertiary syphilis, it is not uncommon to meet with dropsy in several of the joints simultaneously, especially in the knee and elbow, and I believe that such an effect will be more certainly brought about if the individual has been subjected to severe courses of mercury for the cure of the primary

affection. When a strong predisposition to the disease exists, the slightest causes are generally sufficient to call it into action. In weak, strumous subjects, it is occasionally a sequel of typhoid fever, scarlatina, measles, and smallpox. Suppression of the cutaneous perspiration may also induce it; and in many cases it comes on without any assignable reason.

The *symptoms* are generally well marked, the most prominent and reliable, in a diagnostic point of view, being a loss of the natural contour of the joint, and the existence of a soft, elastic, and irregularly circumscribed swelling. The skin ordinarily retains its normal color, and the motion of the articulation, although considerably impeded, is rarely attended with much pain or inconvenience. The tumor affords distinct fluctuation, and is most conspicuous where the ligaments of the joint are loose and superficial. In the wrist, for example, it is most apparent at the anterior and posterior aspects of the joint; in the ankle, in front of the malleolar processes, a short distance above the instep; in the shoulder, in the space between the deltoid and pectoral muscles; in the knee, at the sides of the patella. In the latter, where the swelling is often double, its shape and consistence are materially influenced by the movements of the limb, being softer and more decidedly fluctuating in extension than in flexion. Pressure upon the tumor is seldom productive of much pain; generally, indeed, it causes merely a little uneasiness, or a sense of tenderness. In cases of long standing there is sometimes considerable enlargement of the subcutaneous veins, but this is uncommon.

The progress of these dropsical affections is generally very chronic, many months often elapsing before the tumor attains any considerable bulk. Sometimes, however, the reverse is true; in the knee, in particular, frequently large collections occur within a few weeks. Their march is usually most rapid in rheumatic and gouty subjects, and after attacks of the exanthematous fevers.

In regard to the diagnosis, the history of the disease, the change in the contour of the joint, the fluctuating and indolent character of the swelling, and the comparative freedom of motion of the affected structures, will generally serve to prevent error. If, after the swelling has been thoroughly scrutinized, any doubt exist it may at once be dispelled by the insertion of a very delicate needle, the nature of the escaping fluid being characteristic.

The most important *pathological* changes in this affection, especially in cases of long standing, are opacity and thickening of the synovial membrane, with some degree of vascularity, the vessels being spread over the diseased surface in delicate, arborescent lines, widely separated from each other. Occasionally slight deposits or patches of lymph exist, giving the part a rough, uneven appearance. The cartilages and bones present no perceptible changes, nor do the muscles and other parts around the joint, except that they are more less displaced by the dropsical distension. When the accumulation is very great, the capsular ligaments, pressed upon in every direction, become very much stretched and attenuated. Indeed, in the worst forms of the disease they may be so much distended as to give way, thus allowing the fluid to diffuse itself among the surrounding structures.

The dropsical fluid is generally of a pale, yellowish, straw or amber color, and of a ropy, unctuous, or sero-oleaginous consistence; sometimes it is turbid, whey-like, or sanguinolent, and intermixed with flakes, shreds, or masses of lymph. Its quantity is variable, depending upon the size of the joint, the duration of the case, and other circumstances. In the knee it frequently ranges from sixteen to twenty ounces.

The prognosis is always more favorable, other things being equal, when the swelling is recent and small than when it is of long standing, large, and attended with serious lesion of the synovial membrane. In the latter case the disease is often extremely obstinate, and may become dangerous, as it is liable to be followed by disorganization of the articular cartilages and bones. Ankylosis is not uncommon.

Treatment.—In the treatment of dropsy of a joint it must be borne in mind that it is not a disease, but, like dropsy everywhere else, merely a symptom of disease. Hence, the very first and most important object is to remove the cause upon which the presence of the fluid depends. The question will, therefore, necessarily arise, in every instance, what has been the origin of the affection? Has it been local or constitutional? Upon the success with which this question is answered will mainly depend the success of our remedies.

When the affection is of a purely local nature, as when it is caused by a sprain, contusion, or other injury, topical remedies alone will generally suffice to effect a cure, especially if assisted by an occasional purge and a properly regulated diet. The means to be chiefly relied upon are, perfect quietude of the affected joint, stimulating embrocations, and vesicants. In the milder forms of dropsy, frictions with iodinized lotions, soap lini-

ment, camphorated spirit, and mercurial unguents seldom fail to make a rapid and decided impression upon the absorbent vessels of the joint, as is shown by the speedy diminution of the size and tension of the swelling. They should be rubbed upon the whole of the affected surface twice a day with the bare hand until a decided glow is produced, the parts being well supported in the interval with the bandage, either alone or aided by wet sponge compresses, the compression thus produced powerfully promoting the reduction of the effused fluid. When the absorbents have been fairly roused as denoted by the gradually decreasing volume of the sac, the inunctions may often be advantageously preceded by the cold douche, or by the hot and cold, applied in immediate succession.

When there is evidence of incited action, as when the surface is hot and tender, re-frigerating lotions, consisting simply of cold water, or of water impregnated with acetate of lead and opium, must be employed; for so long as the capillary vessels are in a state of irritation, little benefit can be expected from sorbefacients, properly so called. Even leeching and brisk purgation may then be necessary.

In obstinate cases there is no topical remedy at all comparable to a blister, well sprinkled with morphia, and retained until the epidermis is thoroughly raised. The discharge is promoted by warm water dressings, and the blister is reapplied as soon as the surface is partially cicatrized. This method is much more salutary than that of keeping open the sore with irritating salves, as it exerts a more direct effect upon the absorbent vessels, at the same time that it is much less painful.

Pustulation with tartar emetic ointment and croton oil, so much vaunted by some prac-titioners, is generally hurtful; and as to issues and setons, their employment is never indicated, as the object may always be attained by milder means.

When the affection is of a rheumatic, gouty, syphilitic, or strumous origin, colchicum, mercury, iodide of potassium, and kindred articles, are the means chiefly to be relied upon. Dropsy that is symptomatic of fever, or of some of the eruptive diseases, often disappears spontaneously, as the patient improves in health and vigor, or readily yields to mild measures, particularly tonics, and change of air. Ordinary hydragogue medicines afford little, if any, relief in this affection in any of its forms.

As the joint will necessarily remain weak for a long time after the removal of the fluid, it should be well supported with a gum elastic cap, fig. 597, or a suitable bandage, and kept cool by frequent ablutions with alcohol and water. Fatigue must, of course, be avoided.

Fig. 597.

Finally, when the disease is unusually obstinate, relief should be sought by evacuating the fluid with the aspirator, or by subcutaneous puncture with a delicate trocar or bistoury, inserted in such a manner as to make a valve-like opening, at the most superficial and dependent portion of the swelling, at least two inches from its boundaries, its point being carried along the connective tissue until it reaches the sac. Thus performed, no pos-sible injury can result from the operation, while, by removing the fluid, over which the absorbents have no longer any control, it affords the only chance of relief. The opening is immediately closed with collodion, supported by a compress and bandage; and for some days the limb is kept perfectly quiet, light diet being enjoined, and every precaution taken to prevent inflammation. Reaccumulation is guarded against by the means already indicated.

I have not been so bold as to use injections for the permanent cure of this affection, convinced that the practice must be fraught with danger. The article recommended for this purpose, by Bonnet, Velpeau, and others, is tincture of iodine, diluted with two, three, or four parts of water, introduced subcutaneously with a syringe, to the amount of several ounces, and retained for a few minutes, the joint being pressed slightly during its sojourn, in order to bring the solution fully in contact with the diseased sac. It is then permitted to flow off spontaneously, when the opening is carefully closed, and the case treated upon general antiphlogistic principles. Of the safety, and, consequently, the pro-priety of this operation, great doubt is entertained by many practitioners, and, I think, justly so; for, although it has succeeded in some cases, it is certain that in others it has been followed by such a degree of inflammation as to imperil both limb and life.

SECT. VI.—MOVABLE AND ADHERENT BODIES WITHIN THE JOINTS.

Various kinds of bodies, mostly movable, but sometimes adherent, are liable to form in the cavity of the joints, where, interfering with the functions of the opposing surfaces, they become a source of much annoyance, and sometimes even of intense suffering.

Ambrose Paré, in 1558, was the first to call attention to such bodies, which are divisible into several classes, differing materially in their structure.

1. *Interarticular cartilages*, as they are called, or osseous concretions, are liable to form in various joints, particularly in the ginglymoid, as the knee, elbow, wrist, and jaw, the first, however, being apparently their favorite seat, for it is there that they occur most frequently, and attain their greatest bulk. The orbicular joints rarely suffer ; a circumstance which probably depends mainly upon the conformation of the articular surfaces opposing their development in the one case, and favoring it in the other.

The size, number, form, color, consistence, and structure of these bodies are liable to much diversity. In the knee, they sometimes acquire the dimensions of the patella, or of a hen's egg. Their number is generally in an inverse ratio to their volume. When very large there is often only one, whereas under opposite circumstances there may be several dozens. In one case, as many as sixty were found. The largest number I have ever known to be removed from one joint was thirty-eight, varying from the volume of a pea to that of a pullet's egg. They are, for the most part, of a whitish, grayish, or pale straw color ; while their consistence, like their structure, ranges from that of fibro-cartilage to that of bone, with every possible intermediate gradation. Their shape is generally very materially modified by that of the joint in which they are developed. Thus, in the knee they are often, if, indeed, not commonly, of an irregularly flattened figure, not unlike that of the patella, or they resemble a disk, convex on one side, and concave on the other, in conformity with the outline of the condyles of the femur and the head of the tibia. In many cases, again, even in the knee, they are of a lenticular, rounded, or ovoidal shape. Consisting usually of a single mass, they are sometimes marked off into several lobules, connected together by condensed connective substance. Their surface may be perfectly smooth, or partly smooth and partly rough.

The structure of these bodies varies. In their earlier stages it is generally fibrous, but as they advance in age they assume the character of cartilage, and ultimately that of osseous matter. The process of conversion from cartilage to bone is generally very gradual, and almost always begins in the centre of the concretion, although occasionally it occurs simultaneously both at the centre and at the periphery, or first at the surface and afterwards in the interior. When several such bodies coexist, they often exhibit material differences in their development ; some being comparatively soft, evidently from their cartilaginous nature, and others very hard and osseous.

The immediate cause for these formations is chronic inflammation, leading to the development of neoplasms upon the fringes of the synovial membrane, or to the abnormal proliferation of the articular cartilage, thus giving rise to what is denominated ecchondrosis. The harder varieties, the real osteophytes, as they may be called, have their origin either in the periosteum immediately beneath the synovial membrane, or near the border of the articular cartilage, from which they are gradually detached, and thrust into the affected joint. Finally, there are cases in which, as was shown by the late Mr. Teale, of Leeds, these formations are simply fragments of articular cartilage or bone, separated either by accident or by a slow process of exfoliation consequent upon external violence. The fact that the more ordinary forms of these bodies are susceptible of various transformations shows that they have an appropriate circulation, and also that this circulation continues in force long after they lose their attachment. The period at which they become loose, or floating, depends, no doubt, very much upon the amount of friction to which they are subjected, and the amount of atrophy which they experience after their development has reached the osseous or cartilagino-osseous point. Their original connection is usually effected through the medium of a short, narrow pedicle.

The size and shape of these bodies are well represented in fig. 598, from a drawing of several in a collection of thirty-eight, for which I am indebted to Dr. John T. Berry, of Kentucky, who removed them, without any untoward occurrence, from the knee of a negro, upwards of thirty-five years of age. When quite young, he received a slight injury upon the joint, which, although not painful, was soon followed by considerable enlargement. Two years prior to the operation, he perceived a small round movable tumor immediately above the external condyle, which was followed in about twelve months by two others just above the inner part of the knee. These swellings gave him but little trouble, with the exception of some stiffness in the articulation. Occasionally, however, the external one changed its position, slipping round to the anterior surface of the thigh, above the patella, where it interfered so much with walking that the man was immediately obliged to sit down, and push it back into its original position. An incision being made into the external tumor, the concretions were readily extracted, having all been contained in one sac, of a

dense, firm consistence, which occupied the lower part of the front of the thigh, and communicated with the cavity of the joint. There were thirty-eight altogether, from the

Fig. 598.
Loose Articular Concretions.

Fig. 599.

Adherent Articular Concretions.

volume of a pea to that of a pullet's egg, of a whitish, glistening appearance, rough or pitted on the surface, and of various configurations, as spherical, oval, lobulated, or angular. Fig. 599 exhibits several bodies of this kind as they lie in the joint attached to the synovial membrane, from a specimen in my collection.

The *symptoms* declarative of the presence of interarticular bodies are often characteristic, particularly when these substances occur in the knee. There are, however, on the other hand, cases where the nature of the disorder is so obscure as to elude, at least for a time, the most careful examination. The intruder, if large, generally causes but little pain, whereas, if it be small, and floating, it is very liable to be wedged in between the articular surfaces, so as to occasion severe suffering, followed, if the accident be frequently repeated, by violent synovitis. When, for example, the interarticular substance slips behind the patella, as the patient is standing or walking, he is often suddenly seized with violent pain, which instantly compels him to sit down, in order to save himself from falling. In the night, his sleep is liable to be disturbed by any inadvertent movement of the limb that may favor displacement of the concretion; and when the disease has existed for a long time, and is attended with much relaxation of the ligaments, any accident of the kind, however trivial, is almost sure to produce excruciating agony, often attended with syncope.

When the extraneous substance slips about habitually, it is sure not only to create pain, keeping the joint constantly tender and uncomfortable, but also in a state of enlargement, both by interstitial deposits in the surrounding structures and by increase of synovial fluid. The intumescence, however, is rarely so great as to prevent the surgeon from feeling the concretion, or pushing it about from one point to another. In the knee, it generally forms a marked projection on the side of the patella, more frequently on the external than the internal, its outline being distinguishable both by sight and touch. Cases occur in which, retreating to a particular part of the joint, it remains comparatively harmless, until it leaves its lurking-place and goes to some other, thus causing a renewal of all the former trouble. As the affection progresses, the joint becomes more and more tender, swollen, and feeble; the synovial membrane, constantly fretted by the friction of the concretion, pours out an additional quantity of its appropriate secretion; the ligaments become greatly relaxed, and the patient, at first merely limping, is at length rendered permanently lame and helpless.

The most important diagnostic signs are, the suddenness with which the joint is deprived of its use, the severity of the concomitant pain, the ability of the surgeon to feel, see, and push about the concretion, and the facility with which the patient can generally relieve himself by his own efforts. The chronic nature of the disease, the absence of external injury, and the frequent recurrence of the symptoms from the most trivial circumstances, afford important collateral evidence of the character of the affection.

Although the complaint under consideration is not generally dangerous, yet, as it often materially interferes with the movements of the joints in which it occurs, and does not

admit of permanent relief, except by surgical operation, which is itself always hazardous, we cannot be too cautious in forming our prognosis. The removal of the concretion, unless very small and soft, by absorption, is impossible.

Treatment.—The treatment is palliative and radical. So long as the concretion remains quiet and does not occasion any material inconvenience, or serious embarrassment in the functions of the joint, the most judicious plan is to let it alone, care being taken to support the parts with a gum elastic cap, or some other suitable contrivance, to prevent the substance from slipping about, and thus doing harm. The relief afforded, however, is generally very transient, and, therefore, other and more efficient measures must be adopted.

Two procedures are in vogue for the removal of loose cartilages of the joints, the one being known as the operation by the direct incision, and the other, devised almost simultaneously by Goyrand and Syme, as the subcutaneous method. Concerning the comparative safety of these two expedients various opinions have been expressed; but it is now well ascertained that the preponderance is decidely in favor of the new operation, or the indirect method, while the other furnishes a greater number of cures. Thus, of 216 cases collected by Dr. Hugo M. Benndorf, of Leipzig, in 1868, in which the direct incision was practised, 143 recovered without any accidents, 41 ended fatally, and 32 were followed by bad symptoms. Of 50 cases treated subcutaneously, 28 were cured, 5 perished, 5 had bad symptoms, and in 12 the operation was not completed. It will thus be perceived that the direct method furnishes 81 per cent. of cures, against 66 of the subcutaneous, with 19 per cent. of fatal issues for the former, and 10 per cent. for the latter. The statistics, brought together by Hippolyte Larrey, in 1861, attest the same fact. Of 167 cases, 129 were by the direct incision, and of these 96 were cured, 5 failed, and 28 died. Of 38 cases treated subcutaneously, 19 recovered, 14 failed, and 5 terminated fatally. Mr. Square, of Plymouth, England, had, up to 1871, operated successfully in 24 cases by the indirect method. Dr. G. Gaujot, in 1881, published an analysis of 54 cases treated since 1863 by the direct method, of which only 3 ended fatally; and from all I can gather upon the subject, it may fairly be assumed that, despite its greater danger, the preponderance of authority of the present day is decidely in favor of the direct incision, as affording a better opportunity of removing effused blood than in the subcutaneous operation in which more or less is so liable to find its way into the affected joint, and where its presence is always productive of mischief. In the cases collected by Gaujot, antisepticism did not seem to offer any special immunity from danger. In the time of Benjamin Bell, of Edinburgh, early in the present century, extraction of these concretions was regarded as such a dangerous procedure that that eminent surgeon strongly recommended amputation as far preferable.

One of the great objections to the subcutaneous operation is the difficulty of fixing the floating cartilage in a position favorable to its easy and successful extraction. In this respect, the direct method possesses a decided advantage. Apart from this consideration, experience has shown that the subcutaneous operation, however well performed, is occasionally followed by high inflammation, imperilling both limb and life. It, nevertheless, I conceive, generally merits the preference. Before either operation of so hazardous a character is undertaken the patient should be subjected to a most rigid course of treatment, consisting of perfect rest of the affected joint, with light diet, and an occasional laxative, extending over the better part of a fortnight.

The subcutaneous section of the knee will serve as a type of the operation upon the other joints. The limb being extended upon a table, the foreign body is brought to the upper and outer side of the patella, beneath the large external muscle, where it is to be securely held by an assistant, either with the fingers or with an acupuncture needle, while the surgeon introduces a long, narrow bistoury, from above downwards, into the synovial pouch, which is then freely divided, so as to permit the concretion to be pushed through the opening into the subcutaneous connective tissue, or among the structures exterior to the joint, entirely beyond the serous lining. The puncture is covered with collodion, and a compress is gently bound upon the knee, between it and the concretion, the object being the promotion of speedy union of the edges of the articular wound. The limb is kept perfectly at rest, free use being made of cold water-dressing and other antiphlogistics. When the inner wound is healed, the extraneous substance may be removed by simple incision; or, if not a source of inconvenience, it may be allowed to remain in its new position, where it will soon become imbedded in plastic material, and so prove comparatively harmless. In some cases, indeed, it is speedily absorbed.

In the direct operation, the method now generally adopted, performed under antiseptic precautions, the wound should immediately be closed with the greatest possible care, with

a view to the effectual exclusion of the air, the great danger after such a procedure. If the concretion be still attached, severance should be effected with the knife or scissors, any pulling with the forceps being inadmissible. The remarkable tolerance, even of the largest joints, after free incision practised for such a purpose, is well shown in the case of Dr. Berry, above referred to, in which thirty-eight concretions, some of them of large size, were extracted from the knee at one operation, without a solitary bad symptom.

The after-treatment, in both methods, must be conducted upon the same general principles. During the first eight or ten days the system should be steadily kept under the full influence of opium, the diet should be very light and simple, and the affected joint should be placed in the most easy and comfortable position, free use being made of leeches, vesicants, and lotions of lead and laudanum in the event of inordinate action. If matter form, speedy vent should be afforded. Amputation or resection may be necessary when, after an attempt has been made to save the joint, life is assailed by hectic irritation, pyemia, or gangrene of the limb.

It has been proposed, in cases of loose articular concretions, by different surgeons, more especially by Dieffenbach, Wolf, Jobert, Dumoulin, and Leroy d'Etiolles, to fix the offending substance in a harmless portion of the joint by means of steel pins, serrefines, or subcutaneous wire ligatures, until it has formed firm adhesions in its new situation. The procedure, however, has not met with any favor, as it is not only difficult of execution, but sometimes even dangerous, several instances having been recorded in which it was followed by violent inflammation and even copious suppuration.

2. The movable joints are occasionally the seat of *gouty concretions*, which, from their color and consistence, have received the name of chalk-stones. They are composed of urate of sodium, a peculiar fatty matter, phosphate and carbonate of lime, and a minute quantity of carbonate of magnesium. In one case, that of an old man, I found these concretions in nearly all the principal joints of the body, in small amorphous masses of a whitish color, and of a soft, unctuous consistence. Sometimes the concretions are perfectly smooth and round; more commonly, however, they are rough and irregular, grooved or nodulated. They are generally small, but may acquire the volume of an egg. Their origin is always connected with a gouty diathesis.

The *treatment* of this form of concretion is chiefly constitutional, directed to the removal of the gouty diathesis, with which its origin is so intimately associated. Colchicum and aconite, with an occasional mercurial purge, the free use of lemon-juice, and a diet composed mainly of bread, fish, eggs, milk, and the lighter vegetables, constitute the chief remedies. For a long time, means should be employed to depurate the blood, and to keep up a healthy state of the digestive organs, with an active condition of the renal secretion. If the joint ulcerate, or threaten to do so, extrusion should be effected; in the former case by direct incision, in the latter by the subcutaneous method.

3. The synovial membrane is occasionally the seat of *fibrous tumors*. They occur in different joints, but principally in that of the knee, where several sometimes coexist, varying from the volume of a bean to that of a large almond. On one occasion, I removed a growth of this description fully as large as a pullet's egg. It was of an elongated, flattened, pyriform shape, and was attached, by a short, narrow pedicle, to the upper and anterior part of the inner condyle. The patient, a man of twenty-seven, had labored under synovial irritation for many years, attended with partial ankylosis, and much pain and tenderness, which were always aggravated upon the slightest exertion. A subcutaneous incision being made into the articulation, the tumor was detached by a few turns of the point of the knife, and immediately extracted with a very delicate, slender pair of forceps. The wound, closed with collodion, healed by the first intention, no untoward symptom occurring, as far as the joint was concerned. Some erysipelas, however, appeared upon the skin, and a week afterwards a large abscess formed at the inner and middle part of the thigh, which somewhat retarded recovery. Another tumor, doubtless of a similar nature, was found occupying the deeper portion of the joint, but, dreading further interference, it was thought best not to meddle with it. The functions of the knee were much improved by the operation. The tumor was of a pale greenish color, extremely firm and tough in consistence, smooth, glistening, and somewhat vascular on the surface, and of a distinctly fibrous structure.

4. What is known as the *fimbriated degeneration* of the synovial membrane is sometimes met with, chiefly in the larger joints, as in those of the knee and hip, and consists of innumerable little bodies of all sizes, from a millet seed up to that of a pea, of a pale yellowish or whitish color, and bearing a very close resemblance to the epiploic appendages of the large intestine. Of a smooth, glistening appearance, they stud the free surface

of the synovial membrane in every direction, being connected to it either by a broad base, or, as is more generally the case, by a narrow, slender pedicle. Their structure is evidently of a fibrous character, interspersed with fatty cells, the whole originating in a deposit of plastic matter, which assumes the peculiar arrangement in question in consequence of the friction exerted upon it by the opposing surfaces of the joint in which the substance is effused. The accompanying cut, fig. 600, from Pirrie, affords an excellent illustration of this form of morbid growth.

Fig. 600.   Fig. 601.

Fimbriated Growths of the Synovial Membrane.
The Synovial Membrane of the Knee-joint
Studded with Numerous Melon Seed-shaped
Bodies, the Patella being turned down.

The symptoms occasioned by the fimbriated synovial membrane are altogether of a mechanical character, consisting of pain and stiffness, and of a grating sensation during exercise, along with more or less swelling in and around the joint, from inflammatory deposits. There are no diagnostic symptoms, and the treatment must, therefore, be conducted upon general principles.

5. *Fibroid bodies*, of the size and shape of cucumber, squash, or melon seeds occasionally form in the joints, doubtless in the same manner and from the same causes as the larger concretions. The annexed cut, fig. 601, from Druitt, presents a beautiful illustration of a remarkable case of these peculiar growths.

SECT. VII.—TUBERCULOSIS OF THE JOINTS.

1. GENERAL OBSERVATIONS.

Tuberculosis of the joints, formerly known as white swelling, is an extremely common affection. Beginning either in the areolar substance of the articular extremities of the bones, or in the synovial membrane, or, as, perhaps, not unfrequently happens, simultaneously, or nearly simultaneously, in both of these structures, it is almost peculiar to children under ten years of age, and generally pursues a chronic course, although occasionally it proceeds with so much rapidity as to entitle it to the distinction of an acute malady. However this may be, it seldom stops until it has produced the most extensive textural ravages, consisting in the destruction, either partial or complete, of the affected articulation. Constitutional involvement is usually well marked, especially in the latter stages of the complaint, when it is also not uncommon to find serious lesion of some of the internal viscera, as the lungs, spleen, and mesenteric glands. The disease, as the name

imports, is essentially of a strumous nature, and can, therefore, occur only in persons of a strumous diathesis.

The joints that are most prone to suffer from tuberculosis are the movable, particularly the hip, knee, ankle, elbow, and wrist. Those of the tarsus are also remarkably liable to it. Sometimes several joints are involved simultaneously; and instances occur in which the disease is, apparently, hereditary.

Etiology.—The exciting causes of this affection are generally very obscure, if not utterly inscrutable. The surgeon, it is true, is often told that the patient, perhaps weeks or months before the appearance of the characteristic phenomena, received some injury, as a blow, fall, or kick, or that the affected joint had been sprained, bruised, or twisted; but such information is usually little reliable, or if such an occurrence really did take place, it, probably, exerted little, if any, influence in developing the complaint. Unless very severe, it could no more provoke tuberculosis of a joint than a similar injury of the chest tuberculosis of the lungs, or of the head tuberculosis of the arachnoid membrane.

Exposure to cold, intense or protracted, is particularly liable to prove prejudicial in persons of feeble constitution, with an impoverished state of the blood. The influence of this agency in exciting pulmonary phthisis has long been recognized. Living in damp, underground, ill-lighted, and ill-ventilated apartments operates in a similar manner. Simple suppression of the cutaneous perspiration, suddenly induced, as when an individual is exposed to a strong current of air, is also liable to produce the disease, especially in one predisposed to its occurrence. The use of unwholesome food, chronic disorder of the digestive apparatus, imperfect assimilation, or inadequate nutrition, protracted courses of mercury, and the exhaustion consequent upon copious and repeated hemorrhages, infantile cholera, chronic diarrhœa, scarlatina, measles, smallpox, typhoid fever, and in short whatever has a tendency to enfeeble the system and derange the blood, are so many predisposing causes of the disease, if they do not actually call it into activity.

It has frequently been asserted that rheumatism might induce this disease, but this is questionable. The fact is it is not at all probable that it ever exerts such an influence; for, in the first place, it is well known that tuberculosis is exceedingly uncommon in rheumatic subjects, and, in the second, that, when disease of the joints shows itself in such persons, it is very different from strumous disease.

Persons of fair complexion, light hair and eyes, a delicate skin, and a languid circulation, with a tendency to eruptions of the scalp and enlargement of the lymphatic glands, are most liable to tuberculosis of the joints. In many cases the strumous diathesis exists in a marked degree, the tumid lip and belly, the long eyelashes, the cold extremities, the flattened shape of the fingers, and the disordered condition of the digestive organs, affording unmistakable evidence of its presence.

No one who is in the habit of meeting with this disease can fail to notice the different temperaments of those who are most subject to its attacks. These are, according to my observations, the sanguine and the lymphatic, or a combination of both. In the former, the characteristics are, a rosy hue of the countenance, a well-developed muscular system, with a tendency, frequently, to a certain degree of embonpoint, a vigorous circulation of the skin, warm extremities, and an active state of the intellect. In the latter everything is completely reversed. The face is pale, often swollen and pasty, the muscles are soft and flabby, the feet are habitually cold, the cutaneous circulation is feeble, the pupils are dilated, and the mind is sluggish. In both, but more particularly in the lymphatic, the belly and upper lip are often remarkably tumid, and most expressive of the tubercular diathesis. These two varieties of temperament, with their modifications, deserve careful consideration, as they form the basis of important therapeutic indications in the disease in question.

Morbid Anatomy and Pathology.—The morbid changes induced by this disease vary according to the different stages of its progress, the earlier closely resembling those of ordinary inflammation. The synovial membrane, which is commonly first implicated in the morbid action, affords evidence of slight vascularity, a few delicate, straggling vessels, loaded with blood, being observable upon its surface, with some degree of opacity and softening. An appearance of thickening is often imparted to it, from a deposit of lymph, which, being poured out, perhaps quite freely, soon assumes a pulpy consistence and a pale yellowish or greenish color. Sometimes it is shreddy, tomentose, or filamentous. The articular cartilage, if seriously involved in the inflammation, is of a dull whitish or slightly grayish aspect and somewhat thickened, softened, and partially separated from its osseous connections. The cancellated structure of the bones is abnormally vascular, light, porous, humid, and at the same time easily cut and broken. Not unfrequently its cells are dis-

tended with yellowish tubercular matter, of a semisolid, caseous consistence ; or, this substance presents itself in distinct granules free or encysted, and, perhaps, not larger than a millet seed. The ligaments usually suffer early, being abnormally red, tumefied, and softened. The synovial fluid is generally increased in quantity, but rarely to any considerable extent.

As the disease advances, the alterations become more distinctly defined, for, as the disorganizing process is now in full play, its devastating effects are plainly visible in every portion of the joint. The lymph increases in quantity, and is often intermixed with sero-purulent matter, or thick, greenish-looking pus. The tufts of the synovial membrane are converted into soft, gelatinous, fungous, tubercular granulations, which gradually extend over the cartilage, imparting to it an ulcerated, or worm-eaten appearance, and eventually destroying it. The bony structure is at length also invaded by the granulations, rendering it very red, soft, carious, rough, and fragile. The ligaments exhibit well-marked signs of inflammation, being loose and spongy at one point, attenuated at another, and, perhaps, thickened or hypertrophied at a third. The microscopical appearances of ulcerated cartilage and carious bone, the result of changes wrought during the progress of strumous disease of the joints, are well shown in figs. 602 and 603, from Barwell.

Fig. 602.
Fig. 603.

Section of a Strumous Ulcer of a Cartilage, magnified 500 diameters.
Section of Strumous Tibia, the upper portion exhibiting a mere pultaceous Mass, interspersed with dark Cells. Nucleated cells are often found in the Lacunæ, a very large one, the 1.85 of a line in diameter, is seen in the lower right corner of the cut.

The disease having reached its acme, the structures of the joint are completely subverted, with hardly any trace of their original appearances. Pus is now usually seen, often, indeed, in large quantity, with all the qualities of strumous matter. This, however, is not always the case ; for, at times, it is thick and pultaceous, caseous, ichorous, or sero-sanguinolent. In some instances it is very thin, and almost black, evidently from the effects of the necrosed condition of the bones.

If death take place after a process of recovery has been set up, the joint will be found to be filled by a white, fibrous, organized substance, the extremities of the bones being ankylosed, or firmly attached by the new matter to the surrounding structures. It is very rare for a new socket to be formed, and yet this is not impossible. In time, the artificial joint may admit of considerable motion, but, in general, this is extremely restricted. Occasionally an imperfect ligament is developed around the bony remnants, the surface of which may even become slightly tipped with cartilage. Finally, osseous growths, short, irregular, and friable, sometimes make their appearance upon the bones in the vicinity of the former disease.

The bodies of those who die of strumous disease of the joints usually exhibit serious pathological changes in some of the internal organs, as the direct result of the strumous cachexia, generally so well marked in the latter stages of the complaint. The structures which, according to my observation, are most liable to suffer, are the lungs, the spleen, and the mesenteric and pelvic lymphatic glands, which are sometimes completely crowded

with tubercles, in various stages of transformation. Dropsical effusions are also sufficiently common, especially in the peritoneal cavity and in the lower extremities.

Tubercles and cheesy deposits of the lungs are very common; they often exist in great numbers, especially in the summits of these organs, and they always exhibit the same characters as in ordinary phthisis. Cavities sometimes form, but death usually occurs before they attain any considerable magnitude. The bronchial glands generally participate in the pulmonary disease, being enlarged, softened, and tuberculized. Occasionally extensive adhesions are found between the lung and costal pleura, with or without serous and other effusions. The heart is seldom affected.

The peritoneum is sometimes extensively tuberculized, and considerable quantities of water are often found in its cavity. In children, the lymphatic glands of the pelvis and mesentery are liable to suffer from strumous deposits, and similar changes are occasionally witnessed in the spleen and kidney. In some instances the latter organs undergo the amyloid degeneration. The liver is often cirrhosed and hypertrophied. Now and then the glands of Peyer suffer. Tubercular meningitis is occasionally present, especially in very young children. The pancreas, stomach, bladder, and prostate gland are usually sound. The blood is very thin, and deficient in fibrin and coloring matter. The lower extremities, and even the hands, face, and genital organs, are, at times, anasarcous, especially when the system has been worn out by tubercular disease of different parts of the body.

Tuberculosis of a joint is, as the name implies, essentially a tubercular disease, and consists of tubercular degeneration of the synovial membrane, the result usually of infection from similar deposits beneath the articular cartilage. Modern investigations have conclusively demonstrated that fungous synovitis is not only the expression of a constitutional vice, but that it is frequently the source of general miliary tuberculosis. Some idea of the frequency of tubercular synovitis may be found from the observations of Koenig, of Göttingen, who proved the existence of local tubercles in not less than 69 out of 71 examples of white swelling of the hip-joint. Its malignant or infectious nature is clearly shown by Billroth, who found that 181, or 25 per cent., of 713 cases of fungous synovitis died of pulmonary consumption. These facts have led many modern surgeons to resort to early and complete resection of tubercular joints, with the view of preventing general dissemination of the disease, or to employ parenchymatous injections of weak solutions of iodine or carbolic acid with the hope of destroying the vitality of the tubercle corpuscles. How far this object may be accomplished is an open question.

Symptomatology.—In regard to the symptoms of this disease, they may, for the sake of more definite description, be divided into three stages, all tending from bad to worse.

In the first stage, the patient's suffering is generally insignificant, and is usually referred to the effects of cold, rheumatism, or some slight external injury. The chief complaint consists in some trivial pain, either in or about the joint, not fixed or steady, but wandering and intermittent, and liable to occasional exacerbations. If swelling be present, it is also very insignificant. The joint is usually somewhat stiff, and the patient is easily fatigued by exercise. The general health is unimpaired, or only slightly implicated.

By degrees these symptoms assume a more threatening character; for the disease has now attained its second stage, as is indicated by the changes wrought in the affected structures. The pain is now more severe, as well as more localized and deep-seated, and commonly requires active means for its relief. The patient is annoyed with spasmodic twitches, especially at night, and the affected limb is sensibly wasted and flabby. The joint is the seat of more or less swelling, attended with marked deformity and fluctuation, the result of the presence of an undue quantity of synovial fluid, or of this fluid and of lymph. The parts feel abnormally hot, and there is commonly a peculiar glossy, shining appearance of the skin, which induced the older surgeons to call this disease " white swelling." There is also, in this stage, usually some degree of enlargement of the subcutaneous veins. The constitutional symptoms keep steady pace with the local affection. The appetite and sleep are disordered, the bowels are irregular, and there are occasional paroxysms of fever, with evidences of emaciation and general discomfort.

In the third stage of the disease, the symptoms, both local and general, are strongly denotive of the horrible ravages of the morbid action. The joint and surrounding structures are swollen and enlarged to their utmost, hot, tense, discolored, immovable, exquisitely tender and painful, distended with pus, or pus and synovial fluid, and freely fluctuating under pressure. More or less displacement of the articulating surfaces generally exists, adding thus still further to the deformity. The pent-up matter, gradually approaching the skin, is at length spontaneously evacuated, much to the relief of the parts and

system, but the resulting sinuses, always slow in healing, often continue for years, especially when there is much diseased or dead bone.

The constitutional symptoms in this stage are those of hectic irritation. The patient, at least for a time, has regular vesperal exacerbations, the face is flushed, the pulse is excited, the sleep is impaired, and the surface, during the night, is drenched with copious sweats. Rapid emaciation ensues, the strength declines, and there is not unfrequently colliquative diarrhœa. Thus life may be gradually worn out by exhaustion, or, the discharge diminishing, reaction may take place, followed, sometimes even in apparently desperate cases, by ultimate recovery.

Suppuration, however, does not always take place in this stage of the complaint, or, if it does, there is either very little matter, or, what there is, is so soon absorbed as not to produce any characteristic symptoms. This is the case occasionally even when the greatest ravages have been committed. Sometimes the pus is situated altogether externally, but this is unusual. In other cases, again, also infrequent, it is formed both externally and internally. However this may be, the structures over and around the affected joint always participate in the morbid action, becoming hard, condensed, and enlarged from interstitial deposits.

The matter in scrofulous disease of the joints closely resembles the fluid of a cold abscess, or the pus of a pulmonary cavern, and is often intermixed with small, whitish particles, not unlike grains of soft-boiled rice, flakes of lymph, small clots of blood, and even the débris of articular cartilage, ligamentous tissue, or osseous matter. When long confined, it is apt to be very fetid. Permitted to stand for a while in a vessel, it separates into two parts, one at the bottom, solid and granular; the other at the top, fluid, and of a pale whey-like or oleaginous aspect. When an abscess of this kind has once fully emptied itself, the subsequent discharge is often of a gleety character, ichorous, or thin and bloody.

The quantity of matter may be very small, or so abundant as gradually but surely to exhaust the system. At times the suppuration is almost entirely suspended, perhaps, indeed, for several months, when, either suddenly or gradually, it reappears, and becomes as profuse as before. Once established, it has no special limit as to its duration, but may last, with hardly any intermission, for years. Whenever the discharge is unusually protracted, it may be assumed that there is extensive caries, if not also necrosis of the bony structures of the joint, especially if it be attended with an occasional escape of gritty substance.

Prognosis.—Tuberculosis of the joints is essentially a chronic disease, which, after an indefinite period, terminates either in recovery or in death. The recovery may be complete, both as it regards the part and system, or, the local action disappearing, the joint may be left weak and ankylosed, and the general health regain its original vigor; or, as not unfrequently happens, particularly after the process of disorganization has commenced, both the articulation and the constitution may remain for a long time, if not permanently, in a degraded and crippled condition.

Much, as it respects the result, will depend, in every instance, upon the state of the constitution, the presence or absence of complications, and, above all, the duration of the disease. Age also exercises an important influence, children living longer, and also having a much better chance of recovery, than young adults and middle-aged subjects, in whom, especially the latter, the affection often proceeds with extraordinary rapidity, sometimes ending fatally in a few months. When the constitution is naturally feeble, or when it has been rendered so by the intensity of the local suffering, the probability of an unfavorable termination will be much increased. Imperfect alimentation and intercurrent diseases, as typhoid, intermittent, and eruptive fevers, diarrhœa, dysentery, and erysipelas, often retard recovery, or hasten the fatal crisis. These and other affections, by establishing a drain upon the system, already exhausted by the local disease, are the principal causes of the mortality in tuberculosis of the joints. When the disorder proves fatal without such intervention, it will generally be found that death is directly due to the depressing effects of tuberculosis of the lungs, lymphatic glands, spleen, or peritoneum, so liable to show itself under such circumstances.

Much of the mortality of this disease, as well as most of the bad effects, both temporary and permanent, which it entails upon the affected articulation, results from neglect of appropriate management prior to the commencement of the disorganizing process. Properly treated at its beginning, it is, generally, as remediable as any ordinary chronic inflammation, although not, perhaps, so promptly. The morbid action receding, the effused materials are gradually absorbed, and the parts restored to their normal functions.

Arrived at its second stage, hardly any course of medication, however judiciously applied, will completely avert permanent rigidity, although life may not be at all in jeopardy. The morbid impression has already advanced too far to admit of easy recession ; a certain amount of structural lesion is present, and the patient will be fortunate if he ever completely regains the use of his joint. In the third stage, when the osseous, cartilaginous, and other textures are disintegrated and broken down ; when, perhaps, the interior of the joint is converted into a large chronic abscess ; when the limb is stiffened or immovable, and, finally, when the constitution is worn out by pain and hectic irritation, there will not only inevitably be loss of function, but also great danger of loss of life. If, under such circumstances, the patient survive, his recovery will be effected at the expense of much suffering, too often eventuating in premature decay and dissolution.

Treatment.—In the treatment of this affection, it must be remembered that, as it is generally, if not invariably, merely a local manifestation of a constitutional vice, topical remedies alone will not avail ; to prove efficient and truly useful, they must be combined with, and aided by, means addressed to the general system, with a view to the improvement both of the solids and fluids. It would be idle, in the present state of the science, to insist upon a course so palpably proper in itself and so long sanctioned by experience. We might as well expect to be able to cure consumption, or to ameliorate the condition of a person thus affected, by the exclusive employment of counterirritation and other external measures, as to cure tuberculosis of the joints without the aid of constitutional remedies. Again, in treating this disease it should not be forgotten that it consists of different stages, which, although they run imperceptibly into each other, are, nevertheless, of vast importance in a practical point of view.

Whatever may have been the duration of the disease when the treatment is commenced, the first and most essential element in its management is repose, absolute, unconditional, and persistent, not merely of the joint, but also of the body. Upon this subject there must be no compromise. The slightest departure from this injunction would at any period of the complaint be of great detriment to the patient's limb, while, in its more advanced stages, when the bones and cartilages are seriously involved and matter exists in the joint, it might endanger his life. When the disease is seated in the interior extremity, recumbency must be observed, not for days or weeks, but months.

The local remedies must be regulated by the progress of the affection and the condition of the constitution. If the disease is in its first stage, if the pain is violent and frequent in its recurrence, and if the general health remains unimpaired, we can scarcely fail to derive special benefit from the application of leeches, or, in their absence, from the use of a large blister. The leeches should be scattered over the affected joint, and the flow of blood encouraged for some time with cloths wrung out of warm water. Their number must depend upon circumstances, but, in general, from three to six will be sufficient for a child from three to six years of age. Sometimes a blister may advantageously be applied within a few days after the leeching, and I much prefer this mode of counterirritation to the employment of liniments, embrocations, croton oil, tartar emetic ointment, and iodinized lotions, which is always attended with friction, and for that reason is often prejudicial to the inflamed structures. By these means, conjoined with a plain, simple diet, consisting mainly of farinaceous articles, and an occasional laxative of blue mass and jalap, almost any case may be radically cured in a few months. If fever be present, or if decided plethora exist, as denoted by the state of the pulse, face, and skin, antimonial and saline preparations may be given. To relieve pain and secure sleep, opiates must be used with warm anodyne poultices or fomentations, or, what I have found to be of greater benefit, a lotion composed of soap liniment, laudanum, and tincture of aconite, applied by means of a fold of flannel, kept constantly wet, and covered with oiled silk. Cold applications are generally inadmissible both in this and in the other stages of the disease. When the skin is unusually dry, or the system more than commonly irritable, the localized steam bath, carefully administered, with a Dover's powder at night, is sometimes highly beneficial.

As permanent ankylosis cannot always be avoided, the affected joint should be carefully placed in the best position for future usefulness ; but this is a subject which will receive proper attention in a future section.

Although the treatment now laid down will usually be found to be very serviceable in the earlier stages of the complaint, there is, nevertheless, not a little diversity in regard to the nature of the internal remedies required in different cases. As already stated, there are two distinct classes of patients, the plethoric and the anemic, the former demanding, perhaps, a certain amount of depletion, while the latter will be most benefited

by tonics. I have not met with any cases where I thought the use of the lancet was indicated, and yet I am not prepared to say whether, when the inflammation and pain are very great, in a strong, robust child, soon after the commencement of the malady, venesection, to a small extent, might not be highly beneficial, in preventing suppuration and in saving structure; in general, however, the morbid action may be sufficiently repressed by saline medicines, in union with a minute quantity of tincture of aconite and tartar emetic, assisted, perhaps, by the application of a few leeches to the seat of the disease. In the anemic, a very common class of cases, tonics and stimulants are often required at the very commencement of the disease, consisting either of quinine and iron, or, what is peculiarly valuable, of cod-liver oil, in such doses as shall not prove offensive to the stomach. The diet should, of course, be of a corresponding character, with milk punch, wine, ale, or porter, to rebuild the system, and thus enable the affected parts the more effectually to resist the encroachments of the morbid action.

Absolute rest cannot be employed too soon in the treatment of joint-disease, and must be secured at all hazard, by splints or by extension and counterextension, conducted upon the same principles as in fractures of the lower extremities. The best material for splints is gutta-percha, plaster of Paris, undressed sole-leather, or trunk-maker's board, soaked in hot water, carefully adapted to the parts, and secured with a common roller. When dry, these articles form an admirable case, which may afterwards be padded with cotton, or any other soft substance, to ward off pressure.

Any malposition of the limb, caused by the contraction of the muscles, that cannot be rectified in this way, must be remedied with the tenotome. The effect of such an operation upon the future welfare of the part and system is often most striking, the pain and spasm being relieved as if by magic, and the limb becoming perfectly docile and manageable, especially if extended by the weight and pulley.

In the *second stage* of the affection, the most reliable local remedy is a large issue, to secure a free and permanent discharge of matter. If the case has not been seen before it has reached this crisis, some of the means already mentioned, as leeching and blistering, may be tried; but, unless they be promptly beneficial, no time should be wasted in their employment. The disease is now thoroughly aroused, and must, therefore, be met in the most decisive manner, to prevent its disorganizing and destructive effects. The best place, by far, for the issue is the most prominent part of the swelling, which is usually either directly over the joint or in its immediate vicinity. The nearer, in fact, the discharge is established to the diseased structures, the more likely will it be to be useful. The best issue is one made with the actual cautery, heated white, and gently pressed upon the part until a suitable eschar is formed; one about the size of a twenty-five cent piece if the patient is very young, or twice that size if he is twelve or fifteen years old, being a good average. The slough, which should not extend beyond the subcutaneous connective tissue, generally drops off within the week; and, during this period, as well as afterwards, the parts should be kept constantly covered with an elm or linseed poultice, renewed several times in the twenty-four hours. The discharge, if flagging, may be promoted by savine ointment, by simple cerate containing a few drops of nitric acid to the ounce, or, what I prefer, the occasional application, for a few hours, of a small blister. In this manner an abundant pyogenic discharge may readily be maintained for an almost indefinite period. The cautery may, if necessary, be reapplied at any time during the progress of the treatment.

The hot iron deserves a decided preference, for making an issue in this disease, over all other modes of cauterization, as affording not only a more copious and persistent flow of pus, but, what is of no little importance, making a much stronger, as well as a more permanent, impression upon the part and system. Although it is not always possible to determine how long the suppuration should be kept up, it will be well to let it continue until there is reason to believe that the violence of the morbid action has completely subsided. I have never, in any instance, experienced any bad effects from its protracted continuance; indeed, quite the contrary has been the case. If the discharge becomes offensive, as it often does in warm weather, deodorizers must be used, with a more frequent change of dressing. Occasionally the poultice, especially the linseed, causes painful and itchy eruptions around the sore, necessitating its temporary suspension, or the substitution of some more suitable application.

Besides these advantages, the raw surface left by this kind of issue affords an excellent opportunity for the local application of morphia, for combating the excessive pain and spasmodic twitchings of the muscles, which are so common in this complaint, and which are much more promptly subdued in this way than when this medicine is administered by

the mouth. The quantity necessary to produce the desired effect will, of course, depend upon circumstances; but, in general, from a quarter to a third of a grain will be required for a child three or four years old. Sometimes a dose of Dover's powder will allay the pain and quiet the system more effectually than anything else. The diet should be more or less nourishing, and tonics freely used, if there is marked debility.

When the course of the disease is chronic from its very commencement, as indicated by the absence of heat, spasmodic, starting pains at night, and freedom from suffering on manipulation and pressing the inflamed surfaces together, I know of no measure better calculated to restore the swollen, pulpy, and deformed articulation to its normal condition, than moderate compression exerted by means of the gum ammoniac and mercurial plaster, adhesive strips, or the plaster or water-glass bandage. With such a dressing the patient is enabled to go about on crutches and enjoy the benefit of exercise in the open air.

Professor Hueter, of Griefswald, who has little faith in the ordinary treatment of scrofulous inflammation of the joints, recommends the injection of fifteen drops of a three to five per cent. solution of carbolic acid into the affected bone or articulation in the earlier stages of the disease, or before suppuration has set in. If the remedy fail, he advises total excision. I have myself had no experience in this practice; but have no hesitation in pronouncing it to be entirely too exclusive.

When the disease has reached its *third stage*, the great point in the treatment is to limit suppuration and to promote the absorption of effused fluids, the most important local remedies being dilute tincture of iodine, chloride of ammonium, and cantharidal collodion, along with perfect rest of the affected joint, and the liberal use of anodynes, to allay pain and secure sleep. All active and depressing measures, are, of course, out of the question, as they would only tend to do mischief. If the quantity of pus is small, this treatment may be sufficient to cause its removal, especially repeated vesication; if, on the other hand, the accumulation is considerable, the only thing to be done is to afford artificial evacuation, subcutaneously, if there be as yet no serious structural lesion, or by direct incision when the matter is superficial, and denotive, by its fluctuation and the great size of the swelling, that it is likely, if let alone, to burrow and to produce other mischief. The extension of pus, in such a condition, is always highly prejudicial both to the part and system, keeping up pain, favoring hectic irritation, and rapidly undermining the vital powers. When the matter has been evacuated, whether by a valvular or direct incision, the opening should immediately be closed with adhesive plaster and a thick compress, wet with oil and supported with a bandage, a full dose of morphia being at the same time injected under the skin. When the quantity of matter is unusually great, the best dressing, especially when evacuation is effected by a free opening, is an emollient cataplasm or warm water, medicated with laudanum and sugar of lead. To prevent undue reaction, the system should be steadily kept under the influence of opium, repeated not less than twice a day for at least a week, or until the parts and the system have become accustomed to their new relations. The strength is sustained by tonics and a suitable diet, pure air, and frequent ablutions of the surface with salt water.

If sinuses form, the best plan is not to interfere with them until the patient is sufficiently strong to bear the operation, as the pain and loss of blood consequent upon the use of the knife would, except in rare cases, more than counterbalance any good that might otherwise accrue. Any loose fragments of bone or cartilage should, of course, be promptly removed, and a counteropening may also frequently be beneficial. Washing out the abscess several times daily with weak solutions of chlorinated sodium, permanganate of potassium, nitrate of silver, or similar articles, is especially indicated when the matter is thin, ichorous, and fetid. When the suppurative action is in great measure subdued, the plastic deposits are best dealt with by sorbefacient plasters, as the ammoniac and mercurial, under the influence of which the induration and swelling often disappear with astonishing rapidity. When there is much pain, a suitable quantity of morphia may be incorporated with its ingredients.

In the event of a cure, whether spontaneous or artificial, passive motion must, in due time, be instituted, to prevent ankylosis. The principles upon which it should be conducted are the same as in dislocations and fractures of the joints. Much judgment, however, is necessary, otherwise the operation may readily reprovoke disease. The best plan is to repeat it, at first, only about every fourth day, until the parts have become somewhat accustomed to it, when it may be employed more frequently. As the proceeding is always very painful, especially for some time, it is very important that the patient should be anæsthetized. Indeed, without this precaution, it will be impossible to over-

come the action of the rigid and contracted muscles, or to break up the morbid adhesions in and around the joint.

When the extremities of the bones are necrosed, or so completely carious as to preclude all hope of recovery by time and ordinary means, the soft parts being riddled with sinuses, and the discharge copious and exhausting, excision of the diseased parts will be demanded, and should, if life be not too deeply undermined, be promptly performed, as most likely to rescue the patient from impending death. The disease being thus arrested, the part and system will be placed in a much better condition for gradual and permanent recovery. With proper care it may even be possible to preserve a certain degree of motion between the contiguous bones. Excision is more particularly applicable to strumous disease of the hip and shoulder joints. Good cures, however, occasionally result when the operation is performed upon some of the other joints, although I believe that amputation is always preferable when there is extensive organic lesion, and life is rapidly ebbing away from protracted suffering, or suppuration.

2. TUBERCULOSIS OF THE JOINTS OF THE HEAD AND TRUNK.

1. *Temporo-Maxillary Joint.*—It is not often that this articulation is invaded by this disease, and then almost exclusively in young persons of broken-down constitution, from the effects of cold, mercury, or irritation of the teeth. It is distinguished by a puffy swelling in front of the ear, or in the temporo-maxillary region, by tension and discoloration of the skin, and by a dull, heavy pain in the joint, increased by pressure and motion of the jaw. During the progress of the disease, the auditory canal becomes greatly diminished, if not entirely closed, and the seat of a very fetid, purulent discharge, attended with loss of hearing, especially when there is much involvement of the temporal bone. Finally, abscesses and fistulous openings form, exposing this bone and the condyle of the jaw in a carious or necrosed condition.

In the treatment of this affection special care must be taken to guard against ankylosis, otherwise, when recovery occurs, the functions of the joint may be permanently lost. Dead bone must be extracted as soon as it is sufficiently detached, and the condyle of the jaw may, if necessary, be resected, as in a case under my observation in 1874, in which I removed the condyle successfully in a girl seven years of age. When there is much involvement of the temporal bone, the patient may die from an extension of the disease to the brain.

2. *Clavicular Joints.*—The joints formed by the junction of the clavicle with the sternum and the scapula are occasionally involved in tuberculosis. The disease is met with chiefly in young subjects, and is characterized by the usual phenomena.

When it attacks the sterno-clavicular articulation, the most prominent signs are, a soft, puffy, and elastic swelling at the seat of the disease, and a fixed pain at the same point, aggravated by pressure and motion of the scapula, and also somewhat by forced inspiration and expiration. The head of the collar-bone often presents the appearance of being enlarged. In time an abscess forms, and, if its evacuation is neglected, the matter may descend into the anterior mediastinum, and thus occasion fatal consequences. Luxation of the clavicle can occur only when there is complete destruction of the connecting ligaments, permitting the end of the bone to project upwards or backwards: in the latter case it may compress the trachea and œsophagus.

Tuberculosis of the acromio-clavicular joint is very uncommon, and is characterized by the same symptoms as the preceding disease. Care should be taken not to confound these affections with rheumatism, to which both these joints are liable.

The treatment requires nothing peculiar. Resection of the clavicle may be performed if this bone is extensively necrosed, or otherwise diseased, or if it injuriously compresses the trachea and œsophagus.

3. *Occipito-Atloid and Atlo-Axoid Joints.*—Tuberculosis of these articulations, first accurately described by Schupke, in 1816, and since then specially investigated by Bérard, Teissier, and Schœnfeld, occurs principally in children and young adults, either without any assignable cause, or as a consequence of cold or injury. Although it is essentially similar to Pott's disease, it requires separate notice on account of the peculiarity of some of its effects.

The disease, whether beginning in the synovial, cartilaginous, or osseous tissue, often commits the most frightful ravages, sometimes destroying the greater part of the arch of the atlas, the whole of the odontoid process, and, perhaps, even the margins of the occip-

ital bone.   What is remarkable, the anterior portions of these structures generally suffer much more than the posterior.

In consequence of the destruction of the ligaments, the occipital bone may be dislocated forwards, backwards, or laterally, displacement by rotation being extremely rare.   In whatever direction the accident may occur, the encroachment of the parts upon the spinal canal is seldom sufficient to cause any serious compression of the cord.   The atlas is more frequently luxated than the occipital bone, being thrown either forwards or to one side. Occasionally the displacement is by rotation.   Dislocation backwards is impossible on account of the obstacle offered by the odontoid process.   In the more severe forms of the disease the displacement is sometimes of a mixed character.

The spinal cord is variously altered, according to the nature and extent of the osseous involvement.   In some cases it retains its normal structure, while in others it is softened and broken down.   The dura mater is generally thickened, engorged, fungous, ulcerated, or even perforated, and the arachnoid membrane inflamed and incrusted with lymph.

The disease, at its commencement, is characterized by a dull, aching pain, circumscribed, deep-seated, and much increased by motion and pressure.   A sense of weight and fatigue is experienced in the upper part of the neck, and the patient at length finds it difficult, if not impossible, to support his head in walking.   Gradually other symptoms supervene, the most distressing of which are pain and difficulty in deglutition, dependent upon inflammation of the pharynx.   The neck now becomes deformed, owing to the joint agency of the displacements above alluded to, and of interstitial deposits.   The posterior muscles are remarkably firm and rigid, and the head is immovably fixed, not unfrequently in a very vicious position, being either bent forwards toward the sternum, drawn backwards, or inclined to one side.   When the disease is fully developed, the pain, all along sufficiently distressing, is greatly increased in severity, and radiates about in different directions, especially up into the head and down the neck into the shoulders. When abscesses form, the patient, in addition to the dysphagia, experiences difficulty in speaking, expectorating, and breathing, in consequence of the obstruction of the fauces from the accumulating fluid, and from the same cause the tongue is sometimes partially protruded from the mouth.   The matter is discharged either into the mouth or at the back of the neck ; often by several apertures.   Occasionally large pieces of bone come away with the pus.

When the spinal cord and its membranes are seriously involved, there will be, in addition to the above symptoms, great embarrassment of respiration, lividity of the face, and paralysis, first of the superior, and afterwards of the inferior, extremities ; together, in short, with all the phenomena of a gradual but surely fatal asphyxia.   In some cases the patient perishes suddenly from an accidental twist of the neck crushing the spinal cord.

The deformity of the neck consequent upon this disease is deserving of special notice in a diagnostic point of view.   The affected part is much broader than usual, and also more protuberant or irregular.   When the occipital bone is thrown forwards upon the atlas, the depression which naturally exists at the upper part of the neck, between the attachments of the two trapezial and the two splenial muscles, is effaced, and the finger easily recognizes the posterior arch of the atlas.   If, on the contrary, the bone is forced backwards, the hollow in question will be found to be increased, and the spinous process of the axis less distinguishable.

The displacements of the atlas are generally easy of recognition.   Teissier, who has studied the subject with much care, states that when this bone is dislocated forwards, the spinous process of the axis forms a prominence more marked and nearer to the occipital protuberance than in the natural state, at the same time that the swelling is abruptly interrupted at its upper part, where it is surmounted by an excavation.   When the displacement is lateral, the spinous process of the axis will be found to be more in the direction of a vertical line, extending from the external occipital protuberance.   Finally, one of the articular processes of the axis may give way, and thus form a projection in the neck, either on the right or left side of the middle line.

Tuberculosis of these joints may be simulated by the effects of rheumatism and of external injury, causing pain and stiffness of the neck, with partial, if not complete, immobility of the head.   When the disease is far advanced, the diagnosis is unequivocal.

When recovery takes place, the neck generally remains deformed and protuberant, with great impairment of its functions, the affected bones being completely soldered together by new osseous matter.

In the treatment of this affection, in addition to the employment of the usual remedies, rest and support of the part, by suitable apparatus, are most important elements. The head should lie on a level with the trunk, with a thin, elastic pillow under the neck, and care should be taken, especially in the more advanced stages of the complaint, that it is not suddenly moved in any direction, lest, the ligaments having given way, the bones should become displaced, and thus instantly and fatally crush the spinal cord. The recumbency must be steady and protracted. A circular issue should be established, at an early period, with the actual cautery, directly over the diseased joints, and a free discharge of matter invited. Advancing abscesses should be promptly opened, in particular if they point toward the fauces; if neglected, they may suffocate the patient by their pressure upon the mouth of the larynx, or, bursting unexpectedly, the matter may pass into the windpipe, and so induce fatal asphyxia. If an attempt at reposition of the dislocated bones should be deemed advisable, the operation must be performed with the greatest possible care and gentleness. In the event of recovery, the neck and head must be supported for a long time by a proper appliance, to afford the parts a proper opportunity for safe and perfect consolidation.

4. *Sacro-Iliac Joint.*—The sacro-iliac joint is liable to a very rare form of strumous disease, analogous to coxalgia and white swelling of the knee. It was first accurately described by Boyer, and very excellent accounts of it have been given by Hahn, Nélaton, Erichsen, and Boissarie.

The disease, which is essentially chronic, is most common between the ages of twelve and thirty. Infants seem to be entirely exempt from it. The statistics of Dr. C. T. Poore, of New York, show that children and adults are alike subject to it. Its causes are the same as those of scrofulous affections in general. In the great majority of cases the lesion comes on spontaneously; but an instance now and then occurs in which it is traceable to direct violence, as a blow, kick, fall, or sprain, to the effects of cold, or to suppression of the cutaneous perspiration. Injury done to the pelvic bones and joints during pregnancy and parturition probably predisposes to its production, especially when there is a strong strumous diathesis. Certain occupations may also possibly favor its development. Thus, Hahn has narrated three cases, all occurring in tailors.

The pathology of the disease is sufficiently well understood. Whatever the nature of the exciting cause may be, struma is unquestionably its intrinsic element. In its earlier stages, the disorder is generally limited to the synovial and cartilaginous structures of the sacro-iliac symphysis, these structures becoming eroded, and eventually broken down into a softened, pultaceous substance, presenting a condition not unlike what occurs in the so-called pulpy degeneration of strumous joints, especially that of the knee. As the morbid action progresses, the osseous tissues also suffer, as is evinced by their rough and denuded appearance, by their abnormal vascularity, and by their infiltrated, spongy, and disintegrated character. Caries and necrosis are, however, seldom met with, even in very chronic cases, and the ligaments also retain for a long time their integrity.

The most important *symptoms* are, pain, swelling, lameness, and deformity of the pelvis and limb. To these are superadded, in time, abscesses and sinuses, along with hectic fever, which is generally a prominent occurrence.

Pain is an early symptom; it is seated in the course of the sacro-iliac symphysis, is increased by pressure and motion, and is accompanied by a sense of weakness in the lower part of the back and sacrum. The patient feels as if he would drop apart, and finds it extremely difficult to support himself in walking, very much as in sciatica or rheumatism, for which, at this stage, the disorder is often mistaken. As the disease advances, the pain becomes more fixed and severe, and assumes a dull, aching, or gnawing character. It does not, except in rare instances, extend down the limb, nor is it aggravated by moving the thigh, unless the surgeon neglects to steady the pelvis, when it is often very severe. The gluteal region is somewhat flattened, and tender on pressure, especially as the finger approaches the seat of the disease.

The swelling, originally very slight, gradually increases in extent, and, in time, becomes a prominent feature. It is puffy, elongated from above downwards, and situated in the line of the affected joint; not materially involving the gluteal region, nor invading the natural hollow behind the great trochanter. When abscesses occur, the form and size of the swelling are greatly changed.

Lameness is an early and prominent symptom. The patient, at first, merely limps, and is soon fatigued by exercise. In a very short time, however, his movements become much constrained, and he supports himself with great difficulty, leans forward, and

employs a cane or crutch.   He can put his foot on the ground, but is unable to bear his weight upon it, nor can he twist himself suddenly around without great suffering.   At length his locomotive powers are completely crippled, and he is obliged to keep his bed. Pressure upon the iliac bone, or pushing this bone forcibly against the sacrum, always causes severe pain.

The limb on the corresponding side is, from the very first, longer than the other, the increase in length varying from six lines to an inch or even an inch and a half, according to the duration and violence of the morbid action.   The change, however, is not real, but, as in coxalgia, merely feigned, depending upon the alteration in the position of the pelvis, which is not only considerably depressed, or lower than on the sound side, but also tilted forwards and rotated downwards so as to impart an unusual degree of prominence to the anterior superior spinous process of the ilium.   The limb itself is attenuated, flabby, and enfeebled.   In progression, it is generally somewhat abducted, flexed at the knee, and projected a little forwards, the weight of the body being thrown entirely upon the sound side.   Upon taking hold of the limb, it can be moved in any direction.

By and by, after months of suffering, sometimes, indeed, not until after a year or a year and a half, matter begins to form, preceded by an increase of local and constitutional disturbance, ultimately eventuating in severe hectic irritation.   The swelling over the joint gradually increases in size, and the fluid, which is always of a scrofulous character, slowly burrows among the neighboring parts, spreading underneath the gluteal muscles, in the direction of the great trochanter, extending into the loin or passing into the pelvis, by the side of the rectum, or the rectum and vagina, in the former of which it occasionally finds an outlet.   When this is the case, flatus may enter the cavity of the abscess, and so cause it to become tympanitic.   Sometimes the matter, after having passed into the pelvis, issues at the sciatic notch, and thus gets, as has been observed by Mr. Erichsen, under the gluteal muscles.

The affections with which sacro-iliac disease is most liable to be confounded are, coxalgia, neuralgia of the hip, sciatica, and caries of the spine.   From coxalgia it is distinguished, 1st, by the peculiar shape and site of the swelling ; 2dly, by the character and situation of the pain, which does not affect the limb or knee, as in hip-joint disease ; 3dly, by the tardy progress of the morbid action ; 4thly, by the rotated appearance of the pelvis and the abnormal prominence of the anterior superior spinous process of the ilium ; 5thly, by the persistence of the ilio-femoral crease ; 6thly, by the preservation of the movements of the hip-joint ; and, lastly, by the suffering which the patient experiences when firm pressure or percussion is applied to the innominate bones.   In sacro-iliac disease considerable pain is sometimes perceived at the upper and inner part of the thigh, from involvement of the obturator nerve in its passage through the pelvis.   In both affections there is shortening of the limb, but in the sacro-iliac it is never real at any time, while it is invariably so in the latter stages of coxalgia, owing to the partial destruction of the head and neck of the femur.   Coxalgia is nearly always a disease of early childhood, whereas sacro-iliac disease is seldom observed until after the fifteenth year.

Neuralgia of the hip occurs chiefly in young females of a nervous temperament and hysterical habits, and is, generally, easily distinguished from disease of the sacro-iliac synchondrosis, first, by the character of the pain, which is more widely diffused, as well as more superficial and irregular ; secondly, by the want of intumescence in the course of the joint ; thirdly, by the coexistence of neuralgia in other parts of the body ; and, fourthly, by the history of the case.   Another important element is the absence of abscess, which nearly always occurs in the latter stages of sacro-iliac disease.

The discrimination between sciatica and this affection is seldom difficult.   The chief signs of distinction are that, in the former, the pain is confined chiefly to the lumbar region, while in the latter it is seated more particularly in the line of the sacro-iliac joint. Besides, it is generally more easily amenable to treatment, and is very frequently connected with a gouty or rheumatico-gouty state of the system.   Moreover, in sciatica there is no deformity of the pelvis or change in the length of the limb.

It is barely possible that sacro-iliac disease might be confounded with disease of the spine ; but such an occurrence will readily be avoided if the surgeon keep clearly before his mind the distinction between the real symptoms of the two disorders.   In the former there is always more or less intumescence in the line of the sacro-iliac joint, with marked deformity of the pelvis and elongation of the limb on the affected side ; in the latter all these phenomena are wanting, and the vertebral column is stiff, tender on pressure, and excurvated.   The most common site of the disease is the dorsal portion of the spine, and, if an abscess form, the matter never gravitates in the direction of the sacro-iliac junction.

The prognosis is favorable in the early stage of the disease, and a cure is not infrequent even when matter has formed. Of 58 cases, collected by Poore, 23 recovered; and of 18 in the hands of Sayre, in 6 of which dead bone was removed, all, save one, were restored to health. When the treatment has been neglected, the patient, after having lingered for months, with an occasional intermission from suffering, is finally worn out by the profuse drain and hectic irritation, or by some intercurrent disease, as purulent infection, or tuberculosis of the lungs.

The *treatment* of sacro-iliac disease is similar to that of coxalgia. The principal remedies are rest, recumbency, and confinement of the pelvis, with leeches, iodine, and blisters in the early stages of the disorder, followed, if there be not prompt and decided amelioration, by the establishment of a long issue, with the actual cautery, in the line of the affected joint. Of course, no severe counterirritation is admissible after the parts have become seriously disorganized. If abscesses form, no time must be lost in letting out their contents by a valvular incision. The strength is supported by tonics, and the constitution improved by alterants, as iodide of iron, iodide of potassium, and bichloride of mercury, with cod-liver oil and other suitable means.

Professor McGuire, of Richmond, in 1878, reported two cases of this disease in which great and immediate relief, and, finally, a perfect cure followed the employment of extension and counterextension, conducted upon the same principles as in the treatment of fractures. No counterirritation was used.

3. TUBERCULOSIS OF THE JOINTS OF THE SUPERIOR EXTREMITY.

1. *Wrist-joint.*—The characteristic features of tuberculosis of the wrist-joint are well depicted in the annexed engraving, fig. 604, from Barwell, the disease having already made considerable progress. It will be observed that the greatest amount of swelling and distortion is on the dorsal surface of the hand, although there is also a good deal of fullness in front and in the hollow of the palm, which is often completely effaced, especially when the matter gravitates in that direction. The thumb and fingers are tumefied, stiff, and straight, or nearly so, and have a peculiarly elongated appearance. Every attempt to move them excites severe

Fig. 604.

Tuberculosis of the Wrist-joint.

pain, or pain and spasm. A sense of fluctuation, often very faint and perplexing, is usually perceptible, being most distinct on the back of the joint, and caused either by a fungous condition of the synovial membrane, or by the presence of an unnatural quantity of synovial fluid, or both. The muscles of the limb are wasted and flabby. If matter form, it generally experiences not only great difficulty in finding an outlet, but is very apt to travel up the forearm and down along the dorsal surface of the hand. Dislocation of the bones, in any direction, is uncommon. The head of the ulna, however, is often abnormally prominent, but of the radius the styloid process alone is distinguishable.

The treatment consists in placing the limb in an easy, straight position upon a carved splint furnished with appliances for keeping up extension and counterextension, and in employing the various measures called for in tuberculosis of other joints. If matter form, an early outlet must be afforded, lest it diffuse itself extensively among the soft parts and the bones, and so endanger limb and life. Although resection is sometimes available, the preference should generally be given to amputation.

2. *Elbow-joint.*—Tuberculosis of this joint generally begins in the structures of the humerus, whence it may gradually spread to the ulna and radius, and finally involve the whole articulation. Pain, stiffness, and swelling in and around the joint are the prominent symptoms of the disease. The skin is tense, glossy, and more or less red at the focus of the morbid action; the parts are intolerant of manipulation and motion, and the swelling presents itself in the form of two cones, united on a level with the crease of the elbow, one apex looking upwards, the other downwards. The osseous prominences are completely effaced, except that formed by the olecranon process, on each side of which there is usually a good deal of fluctuation, caused by the presence of a large quantity of synovial fluid. The limb is wasted both above and below the joint, and the fingers are stiff, swollen, and almost useless. The biceps muscle is rigidly contracted, so as to render extension difficult, if not impossible, and the forearm is bent nearly at a right angle with

the arm.   When matter forms, it is usually discharged at the back part of the joint, at the side of the olecranon process, or at the lower part of the arm; seldom in the forearm or in front of the joint. The ulna, owing to the solidity of its connections, is hardly ever dislocated, but it is not uncommon for the radius to abandon its relations with the humerus when there is much disorganization of their ligaments.   In the worst forms of the disease, the bones are involved to a great extent; far, indeed, beyond their articular extremities.

In the treatment of this affection the same principles are to be observed as in articular tuberculosis in general.   Early recourse should be had to the actual cautery, drawn linearly along each side of the joint for three or four inches, and to proper support by means of a suitable splint, extending from near the axilla down to the fingers. The forearm should be placed in a semiflexed position; matter should be promptly evacuated, and every means employed to preserve the usefulness of the limb.   Amputation will be necessary when the disease is very extensive, or the general health is much impaired; otherwise the affected bones may be advantageously dealt with by resection.

3. *Shoulder-joint.*—Tuberculosis of this joint is uncommon, and is met with chiefly in young persons after the age of eighteen or twenty, beginning generally in the synovial membrane and other structures of the humerus, to which it is nearly always limited, the glenoid cavity of the scapula rarely suffering.

The disease is usually announced by more or less swelling, pain, and stiffness in the joint, which the patient is generally disposed to ascribe to the effects of rheumatism, cold, or some slight injury.   As it progresses, the shoulder loses its natural contour, and assumes a peculiarly rounded appearance, owing to the presence of an undue quantity of synovial fluid.   The deltoid muscle is gradually flattened and atrophied, and, in fact, the whole arm is wasted.   The movements of the joint, at first merely restrained, are ultimately entirely lost.   If the morbid action is not arrested, abscesses at length form, point and break, leaving thus a number of fistulous openings leading down to the diseased bone, which is either carious or both carious and necrosed, not unfrequently to an extent of three or four inches.   In the worst cases, there is sometimes serious involvement of the glenoid cavity of the scapula.

The pain which attends this disease, early in the attack, is occasionally most keenly felt in the elbow, as in coxalgia it is originally seated in the knee.   Such an occurrence is, however, uncommon, and, therefore, of little diagnostic value.

The treatment consists in complete repose of the joint, and in the application of leeches and blisters, or, if the attack is obstinate, the hot iron.   Matter is early evacuated, and dead bone or cartilage removed as soon as it is sufficiently detached.   In protracted cases, dependent upon the presence of carious or necrosed bone, the proper remedy is excision; an operation which, if carefully executed, is not only free from danger, but nearly always successful, the patient regaining a good use of his limb.

4. TUBERCULOSIS OF THE JOINTS OF THE INFERIOR EXTREMITY.

1. *Ankle-joint.*—The most common cause of tuberculosis of this joint is external injury, as a sprain, twist, blow, or contusion.   Among the earlier local symptoms is a swelling just in front of each malleolus, filling up the hollow which naturally exists there; it fluctuates under the finger, and is mainly dependent upon the presence of synovial fluid, which, from the peculiar structure of the joint, always accumulates there in larger quantity than elsewhere.   As the disease progresses, the grooves at the side of the tendo Achillis disappear, and the whole joint becomes enormously enlarged, the heel and other osseous prominences losing their distinctive features.   This increase of size is owing, not exclusively to morbid deposits in and around the articulation, but also, at least in part, to an expansion of the ends of the bones, as is easily ascertainable by examination. When the disease is far advanced, the fluctuation is rendered very faint in consequence of the fungous condition of the synovial membrane, the leg is excessively wasted, and the foot has a distorted or twisted appearance, as if it were rotated upon its axis, or partially dislocated.   If suppuration takes place, the matter usually collects in front of the joint, diffusing itself more or less extensively in the subcutaneous connective tissue of that region.

In the treatment of this disease, the foot should be placed at a right angle with the leg, and the parts well supported with suitable splints, so as to maintain them in an easy, relaxed, and quiet position.   Linear cauterization may be performed; or, what is preferable, a small issue should be established with the hot iron immediately above each malleolus.

Prompt vent is afforded to pus ; and, if the joint cannot be saved, resection or amputation is resorted to, according to the judgment of the surgeon.

2. *Knee-joint.*—This joint, owing to the great size of its articular surfaces, its extensive motions, and its exposed situation, is, next to the hip, more frequently the seat of tuberculosis than any other joint in the body. While the disease is most common in young persons before the age of fifteen, it is often met with in young adults, and is generally developed under the influence of external violence, as a blow, fall, or twist, acting upon a depraved constitution.

The pain which attends this disease, and which is generally very severe, even at the commencement of the attack, is almost invariably situated in the direction of the inner condyle of the femur, at the lower part of the patella, or at the inside of the head of the tibia ; seldom at the outer part of the joint. The great uniformity of this occurrence has led to various speculations as to its course, but, as yet, no satisfactory explanation has been offered. As in coxalgia, the pain is liable to periodical exacerbations ; in general, it is of a dull, heavy, gnawing character, and is commonly worse at night than in the day, extending up and down the limb, and destroying the patient's sleep and appetite.

The concomitant swelling is usually very great, and is due partly to interstitial deposits, partly to an inordinate increase of the synovial fluid. It is always most conspicuous, especially in the earlier stages of the complaint, in front and at the sides of the patella, owing to the laxity and yielding character of the tissues at these points. It is in consequence of this circumstance that the depressions in this situation are generally soon completely effaced, or, what is the same thing, replaced by soft, fluctuating bags. A similar prominence, often of great size, exists just above the joint, over the lower part of the femur, bounded inferiorly by the patella, and on each side by the lateral ligament, its anterior wall being formed by the tendon of the extensor muscle. Very little tumefaction ever occurs in the popliteal region, even in the more advanced stages of the disease. The skin is tense and glossy ; the subcutaneous veins are abnormally large ; the knee is stiff, if not immovable ; and the leg, more or less flexed, is swollen and œdematous, while the thigh is remarkably atrophied. In proportion as the ligaments yield, the deformity of the joint increases, owing chiefly to the displacement of the head of the tibia, which allows the muscles to draw the leg outwards, so as to give it a twisted or contorted appearance. Not unfrequently there is an actual enlargement of the heads of the diseased bones.

The fluctuation which constitutes so prominent a symptom in the earlier periods of this complaint, often, in great measure, if not entirely, disappears during its progress, owing to the adventitious deposits upon the synovial membrane and the absorption of the redundant synovial fluid. Whenever this is the case, the swelling, instead of being soft and yielding, will be comparatively firm and resisting, but still possess some degree of elasticity, often so deceptive as to lead to the idea that the joint contains a good deal of fluid, and which nothing but the most careful examination can dispel.

Pus does not always form in this disease, even when permitted to proceed unmolested ; on the contrary, there is reason to believe that it is frequently entirely absent. When suppuration does take place, the matter may either be absorbed, or it may escape at the side of the patella, the lower part of the thigh, or over the head of the tibia ; very rarely in the ham. In the worst forms of the disease, the whole surface of the joint may be riddled with fistulous apertures, leading down to the diseased bones, large portions of which are then either carious or necrosed.

The *treatment* of tuberculosis of the knee presents nothing peculiar. The same rules of practice are to be enforced here as in coxalgia. Rest of the part and system, local support and extension by means of splints and the weight and pulley, and cauterization, either linear or circumscribed, are of primary importance, and must be thoroughly enforced from the very beginning.

When the more acute symptoms have subsided, or the disease has assumed a chronic form, to enable the patient to exercise in the open air, the requisite extension and rest of the joint may be secured by the apparatus of Dr. Sayre, delineated in fig. 605. It consists of two steel collars, each about one inch wide, which embrace the limb—the one at the upper third of the thigh, the other just above the ankle—and admit of adjustment by means of a sliding hinge and lock, while they are connected on each side by an extension rod, constructed on the rack and pinion principle. To apply this instrument, strips of strong, inelastic adhesive plaster, one inch in width, are arranged on the limb in the manner represented in fig. 606, and confined to within an inch of their extremities by a roller.

The instrument is then placed in position, the collars fastened sufficiently tight to be comfortable, and the free ends of the plaster turned over them and secured by a roller. The connecting rods are extended simultaneously by means of the thumb-screws, the limb being thus brought nearly into a straight line, as in fig. 607, freedom from pain, on pres-

sure being brought to bear on the foot, denoting that the requisite degree of extension has been effected. The dressing is completed by enveloping the leg in a bandage from the toes up to the top of the instrument, to prevent swelling, and by surrounding the joint with strips of gum ammoniac and mercurial plaster, so as to exert a sorbefacient action upon the swollen and pulpified tissues. When the parts are hot and painful, the application of the plaster should be preceded by saturnine and anodyne lotions.

When, so far as ordinary treatment is concerned, the case is hopeless, the only resource is resection of the affected joint; or, this being inadmissible on account of the great extent of the disease, amputation of the thigh, which will make a better and more satisfactory cure.

3. *Hip-joint.*—Tuberculosis of this articulation, usually called coxalgia, femoro-coxalgia, or hip-joint disease, is most frequent from the third to the seventh year. Cases occasionally occur before the twelfth month, and now and then an instance is seen after puberty, or even after the age of twenty, but this is uncommon. The oldest case that I have ever witnessed was that of a man twenty-six years of age. Of 1818 cases, analyzed by Dr. V. P. Gibney with reference to this subject, 1602, or 88¼ per cent. were under fourteen years. Both sexes are liable to it, probably nearly, if not quite, in an equal degree, at least such would seem to have been the fact in the cases analyzed by Dr. Gibney; the affection has sometimes been noticed in several members of the same family.

The causes of coxalgia are the same as those which provoke strumous disease in other parts of the body. The most common are external injury, as sprains, falls, or blows, exposure to cold, inadequate food and clothing, and wasting maladies, as cholera, chronic diarrhœa, dysentery, scarlatina, measles, and different kinds of fevers. In many cases it arises spontaneously, or without any obvious causes.

It is seldom that both hip-joints are involved in this affection, either simultaneously or successively. During its progress, however, it becomes occasionally complicated with other strumous maladies, as Pott's disease of the spine, psoas abscess, ophthalmitis, pulmonary phthisis, and degeneration of the lymphatic glands of the neck, mesentery, and other parts of the body.

It is seldom in the power of the surgeon to ascertain the starting point of this disease, as few opportunities occur for examining the parts in the earlier stages of the morbid action. Nevertheless, enough is known to show that the articular cartilage of the head of the femur is the structure which most generally suffers first. In some cases the disease undoubtedly begins in the synovial membrane, in the interarticular or capsular ligament, in the acetabulum, or even in the cancellated tissue of the femur or ilium. However this may be, all the component elements of the joint become sooner or later involved in the disorganiza-

tion, the disease extending from one structure to another, although probably not with equal facility or rapidity.

Symptomatology.—Tuberculosis of the hip-joint may be described as consisting of three stages, each characterized by distinctive symptoms and pathological changes, as well as requiring peculiar treatment. As this division is not imaginary, but real, it is deserving of the greatest attention.

The symptoms of the disease, in its *first stage*, are usually of so obscure and stealthy a character as to render it very liable to be mistaken for other affections of the joint. The first circumstance which commonly attracts attention, especially if the patient is a child, is a feeling of fatigue after exercise, with slight pain in the knee, and a disposition to drag the limb, thus giving the gait a stiff, awkward appearance. In this manner the case may progress for several weeks, or, indeed, even for several months, with, perhaps, hardly any perceptible aggravation. The child still goes about, taking his accustomed exercise, and manifesting the same interest as formerly in his out-door amusements. Gradually, however, the pain increases; there is now a distinct limp; and the sleep is disturbed by spasmodic twitches of the extremity. The pain is usually referred to the knee, particularly to its inner side, and is either sharp and lancinating, or dull, heavy, and aching. It is sometimes felt in the very depths of the joint, but more frequently it is superficial, as if it were immediately beneath the integument. Exercise, or motion of any kind, always increases it, and it is generally worse at night than in the day; damp states of the atmosphere, suppression of the cutaneous perspiration, and disorder of the digestive organs, also frequently aggravate it. The knee, on inspection, is found to be free from swelling and discoloration, and commonly quite tolerant of rough manipulation, as motion, pressure, and percussion. Occasionally the pain is of a neuralgic nature, and distinctly periodical in its recurrence, very similar, in this respect, to the paroxysms of an intermittent fever: the attack, perhaps, coming on early in the evening, and, after having continued for a few hours, returning about the same time next day. This form of pain is most frequent, according to my observation, in persons living in a malarial atmosphere.

It is not often, however, that the pain, whatever may be its character, is entirely confined, at this stage of the disease, to the knee; or, if it is at first, that it remains there exclusively for any length of time. In general, it extends also to the thigh and leg, sometimes along the front, now along the sides, especially the inner, and now along the posterior surface, in the direction, apparently, of some nervous trunk, as the femoral, obturator, saphenous, or sciatic. I have met with cases where the pain was felt most keenly at the tendo Achillis, immediately above the ankle-joint, and in one instance it was distressingly severe over the instep. Sometimes, again, it seems to shift from one of these points to another, being, perhaps, most violent at one period in the knee, and at another in the thigh, leg, or foot.

The occurrence of pain in the knee may be explained by the irritation of the nerves that are distributed to the hip-joint. Thus, the round ligament receives a filament from the obturator nerve, which sends a branch to the inner side of the knee as well as to its interior. Inflammation of the synovial covering of the ligament necessarily involves its nervous supply, and the sensation of pain is experienced either at the inner side of the knee or in the interior of the joint. When the anterior portion of the capsule and its synovial membrane are primarily affected, the suffering is generally referred to the outer side of the knee, as branches are distributed to that locality from the femoral nerve, which also sends articular branches to the front of the hip-joint. Anomalous pains experienced at other situations may also be explained by nervous irritation. The posterior portion of the hip-joint is supplied by filaments from the great sciatic trunk, which sends branches not only to the back of the knee, but to the entire lower extremity, so that pain may be felt at any of the points supplied by that nerve, when the inflammation is seated at the posterior surface of the articulation. A knowledge of these anatomical facts renders great aid in the diagnosis of individual cases, and serves to prevent those curious mistakes, which not unfrequently occur, of medicating parts which are free from disease.

After some time, varying from a few weeks to as many months, the pain shifts to the hip and its neighborhood; or, if it do not entirely forsake the knee, it is generally less constant and severe there than it was in the first instance, or soon after the commencement of the morbid action. Commonly it is most intense and persistent directly over the articulation, deep-seated, and of a dull, gnawing character. At times it is perceived most keenly in the sciatic notch, between the great trochanter and the spine of the ilium, or in the upper and outer part of the groin. Occasionally, again, it exists simultaneously at all these points, although not in an equal degree; or, as it leaves one, it fastens itself upon

another. In rare cases the pain appears in the hip before it shows itself in the knee, thigh, or leg. Pressure upon the gluteal region and the groin, motion of the affected joint, and percussion of the knee, the leg being flexed at a right angle, or of the sole of the foot, the limb being extended, always augment the pain, and lead to the detection of its seat.

As yet, there is no sensible impairment of the general health; the appetite is good, and the various tissues retain their normal condition. The muscles of the affected hip and limb are, perhaps, a little thinner and softer than natural, but these changes are usually slight, and hence they often elude detection.

In the *second stage* of the complaint, the most prominent local phenomena are, an increase of pain in the hip and knee, flattening of the buttock, effacement of the gluteo-femoral crease, abduction, outward rotation, and apparent elongation of the limb, with spasmodic twitching and wasting of its muscles.

The pain, hitherto seated chiefly in the knee, now also affects the hip, or, if it existed there previously, as, indeed, is not unfrequently the case, it becomes sensibly aggravated. It is particularly violent at night, often for hours interrupting sleep, and is attended with the most distressing spasmodic twitches of the muscles of the limb, which thus greatly augment the local and general suffering by the sudden and forcible apposition of the inflamed articular surfaces. The pain at one time is fixed, deep, aching, gnawing, or boring; at another, erratic, sharp, or lancinating, darting about in different directions, now through the joint, then down the limb, and then through the groin, or back along the course of the sciatic nerve. It is most distressing when the bone is inflamed immediately beneath the articular layer, and sets in much earlier than when the synovial membrane is primarily affected, thereby furnishing a clue to the diagnosis as to which of these structures is first involved. Occasionally it is most severe in the lumbar region, in the lower part of the pelvis, in the situation of the acetabulum, or at the upper and inner part of the thigh. Sometimes, as before remarked, it is of a neuralgic character, coming, going, and recurring at particular periods. Derangement of the digestive apparatus, exposure to cold, and damp states of the atmosphere, have a tendency to aggravate and protract it. The pain in the knee, instead of disappearing, generally increases in violence, at the same time that it becomes more frequent and fixed.

Fig. 608.

The sleep is habitually disturbed by unpleasant dreams, and the patient often wakes up in great alarm, crying and screaming. Occasionally he is partially delirious from pain and fever. He sleeps by snatches, and usually feels fatigued and unrefreshed in the morning. Spasmodic twitching, jerking, or starting of the limb is a prominent symptom, seldom entirely absent in any case. Sometimes, indeed, it sets in at a very early period, and continues, with more or less violence, during the whole progress of the malady. It is particularly distressing in the muscles of the thigh, but often affects also those of the hip and leg.

Along with these symptoms there is frequently loss of appetite, with disorder of the secretions, and more or less fever at night. The bowels are usually inclined to be constipated, the urine is scanty and high-colored, the skin is rather arid, especially in the evening, and there is often considerable thirst. As the disease advances, the fever increases, and is frequently followed by copious sweats. The patient loses flesh and strength, he is peevish and irritable, and his countenance has a care-worn appearance. Although such is ordinarily the state of the system, in the second stage, especially after the disease has made considerable progress, yet there are cases in which there is hardly any constitutional disturbance whatever, except what results from the want of sleep.

The local phenomena at this stage of the malady are unmistakable. The buttock of the affected side is found to be remarkably flattened, as is shown in fig. 608, so as to be in striking contrast with the sound one. It is much broader, as well as considerably longer, than in the natural state; the gluteal muscles are soft and flabby, and the skin is preternaturally loose, from the absorption of the subcutaneous fat. The gluteo-femoral crease, so

Appearance of the Nates and Limb in Hip-joint Disease, in its Earlier Stages.

prominent in the natural state, is completely effaced, giving the thigh and hip an appear-

ance of continuity, as if they were fused together, and the internatal fold is inclined towards the affected side. The muscles of the thigh and leg are also wasted, and, in fact, the whole limb is very sensibly attenuated, evidently owing to want of exercise and perverted nervous action, leading to atrophy of their substance.

Marked elongation of the corresponding limb, with abduction and outward rotation, now exists, and is so constant an occurrence that it may, along with several of the other symptoms above described, be considered as pathognomonic. The extent of the elongation varies, on an average, from half an inch to an inch and a half. In rare cases it may amount to two inches, and even two inches and a half. It is observed both in the erect and in the recumbent posture, but is commonly more conspicuous in the former than in the latter. Several explanations have been offered of this phenomenon, all, at first sight, more or less plausible. Thus, it has been attributed to the presence of an unusual quantity of synovial fluid, the product of inflammatory action, by which the head of the thigh-bone is partially pressed out of its socket, and the corresponding limb projected beyond the level of the sound one; but that this theory is not true is proved by the fact that there are frequently large accumulations of this kind in other joints, as the elbow and knee, without producing any such effect. That it is due to a relaxed condition of the ligaments and muscles of the joint is also, I am persuaded, an unfounded idea. A third opinion, and, in my judgment, the only correct one, is that the elongation is due to the position of the pelvis, which, through the agency of the abductor muscles of the thigh, is thrown downwards and forwards, thereby producing a difference in the level of the two hips, that of the affected side being always lower than that of the sound side.

Finally, there is generally, in this stage of hip-joint disease, a marked depression, or hollow, in the lumbar region, with a slight inclination of this portion of the spine toward the sound side, and an unusual prominence of the belly. The inferior portion of the spinal groove is also more distinct than natural.

In the *third stage* the nature of the disease is no longer doubtful, whatever it may have been previously. The symptoms are characteristic of the extensive and frightful mischief that has been effected within the joint. Matter now forms, and, by its pressure upon the inflamed structures, greatly aggravates the suffering. The suppuration is indicated by an increase of pain; by a sense of throbbing and tension, deep and persistent; by severe swelling of the gluteal region, generally most prominent at the centre of the articulation; by œdema of the subcutaneous connective tissue; and by a remarkably turgid and enlarged condition of the subcutaneous veins. The affected joint is intolerant of the slightest motion or manipulation, and the patient is unable to raise himself up or turn in bed without the greatest agony. Every attempt to flex or extend the limb is attended with similar results. The constitutional disturbance is always in proportion to the local suffering, and violent rigors, followed by high fever and copious sweats, are rarely absent. Sometimes, however, the abscess forms in a quiet and insidious manner, without any of the severe symptoms that usually accompany the suppurative process in this and other varieties of inflammation. As the matter increases in quantity it gradually works its way towards the nearest surface, its approach being denoted by the occurrence of a circumscribed, erysipelatous blush. Here there is generally distinct fluctuation, and the parts, feeling soft and boggy, soon yield at one or more points, followed by the escape of the contents of the sac.

The site at which the matter, when left to itself, obtains a vent, varies in different cases. Most generally it escapes at the gluteal region, either directly over the joint, or in its immediate vicinity. The other situations at which it is most liable to discharge itself are the upper and back part of the thigh, a short distance below the great trochanter, the superior and external part of the groin, the sciatic notch, and the upper and inner surface of the thigh. Occasionally it escapes at several points, either simultaneously or successively, leaving thus a number of orifices, with a corresponding number of sinuses. These passages are sometimes very long and tortuous, and in old cases are always lined by a false membrane. I recollect one instance in which there were nine distinct openings, and another in which there were as many as twelve; two at the upper part of the thigh, and one just below the crest of the ilium, the remainder being scattered over the gluteal region.

The matter sometimes escapes both externally and internally. When the bottom of the acetabulum is perforated, it may pass into the rectum, bladder, or vagina; or, instead of this, it may collect in a sort of pouch, between the inner surface of the iliac bone and the soft parts of the pelvis.

The changes in the limb and hip, represented in fig. 609, in this stage of the disease, are striking and characteristic. The extremity, now actually shorter than natural, is much attenuated from the wasting of its fatty and muscular tissues, and remarkably disfigured in its appearance, the heel being considerably elevated, and the ball of the foot and toes alone touching the ground when the patient makes an effort to stand. The degree of shortening is variable, and not always by any means in proportion to the destruction of the head and neck of the thigh-bone, the acetabulum, and the connecting ligaments, which forms so prominent a feature of the disease at this period. While in some instances it does not exceed an inch, or, at most, an inch and a quarter, in others it amounts to twice and even thrice that extent. One-third, and sometimes even one-half of this, as I have satisfied myself by careful examination, is generally attributable to the elevation of the pelvis on the affected side. The position of the foot is variable. Sometimes it looks directly forwards or outwards, but much more commonly it inclines inwards. These differences are due to the nature and extent of the ravages experienced by the hip-joint. When the acetabulum has suffered most severely, the foot usually turns more or less out; if, on the contrary, there has been much destruction of the head and neck of the femur, and the cotyloid cavity is only slightly involved, the limb generally inclines strongly inwards, as in traumatic iliac luxations.

Fig. 609.

Shortening, Swelling, and Characteristic Deformity of the Advanced Stage of Coxalgia.

The thigh is generally bent upon the pelvis, the angle of flexion varying from the slightest perceptible change to 45°. In most cases it inclines somewhat towards the sound limb, and occasionally, although rarely, it overlaps or crosses it. Sometimes, on the other hand, it stands off widely and in a most unseemly manner from its fellow, as in the case of one of my patients, a woman, aged twenty-five, in whom the knees were habitually upwards of fifteen inches apart, the affected thigh forming a right angle with the pelvis, while the foot, in the erect position, was at least six inches from the floor.

The thigh, moreover, is always in a painfully rigid state, depending upon the contracted condition of the muscles of the hip and limb, and the formation of adhesions between the remnants of the superior extremity of the femur and the surrounding parts. By taking hold of the knee, a slight degree of flexion may, perhaps, be produced, but to abduct the thigh, or to move it backwards, is generally impracticable; besides, every effort of the kind is attended with excruciating suffering. Owing to the shortening of the hamstring muscles, the leg is commonly bent on the thigh, and, for the same reason, the flexor muscles usually draw the heel upwards towards the leg. In all confirmed cases of hip-joint disease, there is invariably a compensating curve in the lumbar or dorso-lumbar portion of the spine, caused by the manner in which the patient holds himself in sitting and walking.

The great trochanter generally lies directly over the acetabulum, or in its immediate vicinity, forming a hard, firm, immovable, or nearly immovable, prominence, the nature of which cannot be mistaken. In regard to the head and neck of the femur, they are, as stated elsewhere, usually completely annihilated, or so much wasted as to exist only in a rudimentary form. It has generally been alleged that there is, in this stage of the disease, more or less displacement of this bone; but the facts collected by the late Dr. March, of Albany, in the extensive museums of the United States and of Europe, as well as in private practice, conclusively prove that dislocation of the femur, as a consequence of this affection, in any direction, is exceedingly rare. A true luxation, such as occurs in the normal state of the parts from injury, is, in fact, impossible, from the very nature of the morbid alterations in the superior extremity of this bone. During the progress of the disease, the remnant of the neck, which is usually of a rounded, conical shape, and frequently not more than three-quarters of an inch in length, ordinarily places itself over the acetabulum, to the margins of which, and to the adjacent parts, it becomes, in the event of recovery, ultimately united. That it is occasionally drawn up beyond this point, especially when there has been complete destruction of the upper border of the acetabu-

lum, backwards towards the sciatic notch, forwards upon the pubic bone, or downwards and forwards into the thyroid foramen, is unquestionable. Dislocation, however, in most of these directions, can only take place in those cases where there has been extensive suppuration, with separation or destruction of the soft parts, allowing the superior extremity of the bone to move about, in search, as it were, of a new position. The upward displacement is, undoubtedly, the most frequent, but even this is extremely rare. In one of my cases the end of the thigh-bone projected above the acetabulum, where it had formed for itself a superficial socket in the iliac bone, admitting of very slight motion. The true cause, then, of shortening, in the third stage of the disease is not dislocation, but destruction, partial or complete, of the head and neck of the thigh-bone, along with a certain degree of elevation of the corresponding hip.

The changes produced in the affected limb by upward displacement are strikingly illustrated in fig. 610, from a clinical case. The foot is inverted and elevated, the ball resting

Fig. 610.

upon the opposite instep; the knee is bent, and in advance of its fellow; the thigh is firmly flexed on the pelvis, rotated inwards, and adducted, its axis forming an acute angle with the transverse axis of the pelvis; the limb is shortened to the extent of two inches and a half, the amount of true shortening, however, amounting, by actual measurement, to only one inch; the buttock is more full than normal, and pointedly prominent at its external and upper portions; the gluteo-femoral fold is drawn upwards, and the internatal crease is inclined towards the sound side; while the summit of the great tro-

Fig. 611.

Upward Displacement in the advanced Stage of Coxalgia.
Extensive Malposition of the Limbs in the advanced Stage of Coxalgia.

chanter lies above its natural level. Fig. 611, from Druitt, exhibits, in a striking degree, the extraordinary attitude which the limbs may assume in the advanced stages of coxalgia. The dotted lines indicate the course of the incisions made in the removal of the head of the diseased bone.

The state of the general health, in this stage of the disease, is in strict accordance with the local ravages. The pallid countenance, the wasted muscles, the impaired appetite, the loss of strength and sleep, and the copious night sweats, too clearly indicate the exhausted condition of the system, and the gradual approaches of death. Serious complications, as colliquative diarrhœa, dropsical effusions, and pulmonary phthisis, often arise during the progress of the case, and thus greatly aggravate the suffering. Excessive anemia is nearly always present. Serious disease of the liver occasionally exists, the organ being enlarged, congested, and in a state of fatty or amyloid degeneration. The kidneys are also sometimes extensively involved, but, on the whole, less frequently than might be supposed. They are most liable to suffer when the system is pervaded by the tubercular dyscrasia.

Diagnosis.—Although the symptoms of this disease are usually well marked, especially if some time has elapsed, it is extremely liable to be diagnosticated erroneously.

The inexperienced practitioner, misled by the seat of the pain, too often contents himself with a most superficial examination, and, taking this as the basis of his therapeutic indications, is very apt to misapply his remedies, addressing them, perhaps, solely to the knee, which is only sympathetically involved, when they ought to be directed exclusively to the hip, the actual seat of the morbid action. Numerous cases, illustrative of the truth of this remark, have fallen under my observation, and there are few surgeons in extensive practice who have not, like myself, had occasion to lament the great mischief that has thus been entailed. In a malady so grave as this an error of diagnosis may be fraught with the worst consequences both to the part and system, eventuating, as it necessarily must, in the loss of precious time ; for it but too often happens that, when the true nature of the disease is discovered, all our efforts to arrest its progress are unavailing.

The affections with which this disease is most liable to be confounded, or which may, at least for a time, obscure its diagnosis, are sprains and rheumatism of the ilio-femoral articulation, psoas abscess, purulent collections in the vicinity of the hip and in the upper part of the thigh, and inflammation of the periosteum of the great trochanter.

A *sprain*, twist, or contusion of the hip-joint may, if followed by considerable inflammation, give rise to severe pain and stiffness, seriously weakening, if not completely disabling, the part. The patient, in attempting to walk, raises the hip of the affected side and relaxes the corresponding limb, by bending the knee and retracting the heel, very much as in the earlier stages of tuberculosis. The muscles, also, by degrees become flabby and attenuated, and there is a sensible diminution of the temperature of the cutaneous surface. The gluteo-femoral crease is eventually effaced, and even the general health may suffer. The signs of distinction are, the history of the case, the absence of pain in the knee, the greater latitude of motion, the absence, in general, of constitutional disturbance, and, lastly, the fact that the foot, although everted, is usually easily rotated on its axis, whereas in strumous disease of the hip-joint, it is commonly pretty firmly fixed.

Rheumatism of the hip-joint, chronic and subacute, is generally caused by cold, or by sudden suppression of the cutaneous perspiration, and is seated principally in the ligamentous and synovial structures, the cartilaginous and osseous being seldom involved, except in very severe and protracted cases. The pain, which runs down the front of the thigh, is dull, heavy, or aching ; the gait is limping ; the pelvis is higher on the affected side than on the sound, and the limb exhibits, in the main, the same attitude as in lameness from sprains and contusions, with this peculiarity that the foot is always strongly everted, while in the former case it is generally inclined inwards. The patient in the morning complains of stiffness in the hip, which usually diminishes very sensibly after exercise, but is sure to return in the evening if there has been much exertion or fatigue. The muscles of the thigh are attenuated, but more firm than in tuberculosis, while those of the leg often retain their normal bulk ; the gluteo-femoral fold is effaced ; the limb, owing to the obliquity of the pelvis, appears shorter, often from one to two inches, than natural ; the great trochanter is uncommonly distinct ; and a creaking noise is generally heard if the head of the thigh-bone is forcibly moved upon the acetabulum. Now, although these phenomena bear a very close resemblance to those of strumous disease of this articulation, yet the absence of severe suffering at night, and at all times at the knee, the marked relief afforded by gentle exercise, the trifling annoyance from pressure, percussion, and motion, even when rudely performed, and the rarity of rheumatism in children, together with the frequent coexistence of this disease in other parts of the body, will generally be sufficient to prove that the affection is not tubercular.

It is not often that *psoas abscess* is mistaken for coxalgia ; for, although the matter which is formed in its latter stages occasionally points at the outside of the groin, or at the upper and inner part of the thigh, there is always the most marked difference in the character of the two swellings, independently of other symptoms. In psoas abscess the tumor is usually, at least in its earlier stages, situated above Poupart's ligament, while in hip-joint disease it is commonly below ; in the former it always sensibly diminishes and sometimes even entirely disappears under pressure and recumbency, but quickly reappears when the pressure is removed, or when the patient raises himself up ; in the latter, on the contrary, it never changes its position, or, if it do, it is in consequence solely of the force of ulceration, absorption, and gravitation ; in psoas abscess the swelling receives a distinct impulse on coughing, laughing, and crying, which is not the case in tuberculosis of the hip-joint.

Again, in psoas abscess the principal pain is in the loins ; it is fixed there, and is

always greatly increased by the erect posture, as well as by every attempt to extend the corresponding limb. In coxalgia the pain is most severe in the knee, or in the knee and hip. In psoas abscess there is at no period any change in the position of the great trochanter, nor any alteration in the length of the limb; in hip-joint disease, on the contrary, especially in its more advanced stages, these are prominent symptoms. Finally, psoas abscess occurs nearly always after puberty, whereas the other affection is most common in early childhood.

Sometimes large deposits of *pus* take place in the connective tissue of the nates, or beneath the gluteal muscles, and, forming a prominent tumor in the direction of the ilio-femoral articulation, may thus simulate abscess of the joint from tuberculosis. These accumulations are commonly the result of external injury, or of a phlegmonous, rheumatic, or erysipelatous state of the system, and are, therefore, in general, easily distinguished by their history, by the rapidity of their progress, by the severity of the local distress, and by the comparatively prompt recovery of the parts after the evacuation of their contents. Cold abscesses of the nates, besides being exceedingly infrequent, exhibit none of the diagnostic signs of articular disease, especially such as pain in the knee, or pain in the hip-joint upon rotating the thigh, so characteristic of the latter malady. It is only when they depend upon caries of the innominate bone that the distinction would be likely to be attended with difficulty, and in this case a thorough exploration with the probe would probably furnish the requisite light.

Finally, diagnostic embarrassment, to an annoying extent, occasionally arises from *periostitis* of the great trochanter, especially in persons of a rheumatic or gouty habit of body. The fibrous membrane of this portion of the femur becomes exquisitely painful and tender to the touch, under the slightest motion and percussion, and the disease, extending above the neck of the bone and the capsular ligament of the joint, causes distress and difficulty in walking, with elevation of the corresponding side of the pelvis, similar to what is seen in coxalgia. The soft parts around are swollen and puffy, giving the hip an increased breadth and thickness; by and by suppuration takes place, sinuses form, and small portions of the bone separate and come away. Unless the case is well managed, the joint is rendered stiff, and the patient does not regain his health for a long time. The signs of distinction are, the persistence of the gluteo-femoral crease, the coexistence of rheumatism or gout in other regions, and the fact that the disease usually occurs later in life than coxalgia.

Effects similar to those of rheumatism of the great trochanter sometimes arise from inflammation of the *synovial bursæ* in this situation. The affection is characterized by pain, tenderness, and swelling, by flexion of the thigh upon the pelvis, by difficulty in progression, and by other symptoms simulative of coxalgia. The disease, which occasionally terminates in extensive suppuration, is most common in young, strumous subjects, and is often directly due to external injury, as a blow or fall, causing severe contusion of the parts. The diagnosis rests mainly upon the history of the case, and in thorough exploration of the joint and neighboring structures.

But it is chiefly in the very early stages of this affection that erroneous views of its diagnosis are liable to be formed; when it is fully established, the phenomena are generally too well marked to be mistaken. It has been seen that the very first symptom, in every case, is pain in the knee; so uniform and constant, indeed, is this occurrence, that it must be regarded as pathognomonic, and yet, as was previously stated, it rarely happens that it is referred to its true source. Instead of being considered as an expression of disease of the hip-joint, it is too often regarded merely as an effect of neuralgia, rheumatism, or injury of the knee, to which, accordingly, the treatment is exclusively directed. Its great value, as a diagnostic, is totally overlooked, and thus the disease is allowed to progress at the only time almost when it admits of prompt and radical cure.

In order to avoid this serious and too common mistake, a most thorough examination should be made in every case presenting the slightest suspicion of the existence of tuberculosis of the hip-joint. The very fact that there is pain in the knee, severe in degree, and of frequent recurrence, should of itself excite the alarm of the surgeon, more especially if, added to this, there is a limp in the gait, an increase of suffering after slight exercise, and disturbed sleep at night. If the diagnosis is obscure, the examination must be repeated, again and again, until it is perfectly cleared up. To conduct the investigation properly, the patient must be completely stripped, and viewed both behind and in front, as he stands on the floor. If there is any flattening of the nates, unusual prominence of the trochanter, or change in the gluteo-femoral fold, it will be sure to be detected, and so, also, if there is any alteration in the attitude, size, or length of the corresponding

limb. If the patient be now requested to walk, the amount of limping will be discovered, as well as the manner in which he raises and moves the leg and foot. To complete the investigation, the patient is stretched out on the floor, or on a hard lounge, with a view of ascertaining the amount of suffering produced by rotating the head of the thigh-bone upon the acetabulum, and also by bringing these parts forcibly into contact with each other by percussing the knee, the leg being flexed, or the sole of the foot opposite the ankle, the foot being bent on the leg. The patient being next turned upon his abdomen, the hip is thoroughly examined, first, with reference to the condition of its soft parts, and, secondly, as to the amount of sensibility of the component structures of the joint; finally, if there is any obliquity of the pelvis, it may easily be observed both in the erect and in the recumbent posture; while any change in the length of the affected limb may be determined by extending a piece of tape, or other suitable band, from the anterior superior spine of the ilium to the inner side of the lower extremity of the patella, or from the former point to the sole of the foot, placed at a right angle with the leg. The difference in the length of the measure on the two sides will give the difference in the length of the affected and sound limbs. Actual shortening may generally be easily detected by laying the patient upon his back, and raising the knees at a right angle with the pelvis, where it will be seen that the one on the side affected does not project as far up as the one on the sound side. The attitude of the limb generally affords important information. Early in the disease it is usually slightly abducted, and rotated outwards, whereas in the more confirmed stages, especially when the head and neck of the femur have been partially or completely destroyed, it is always strongly adducted, as well as materially shortened, very much as in a traumatic iliac luxation. There will also, in such a case, be unusual prominence of the great trochanter, and great elevation of the heel. The situation of the sinuses which form during the progress of coxalgia deserves careful consideration in regard to the seat of the osseous disease, or the particular bone involved in the morbid action. Thus in a general way, it may be inferred that, when the track lies at the upper and outer part of the thigh, in the direction of the tensor muscle, the upper extremity of the femur is the bone affected; when the sinus opens upon the gluteal region it implies the existence of disease in the iliac bone, or in this bone and in the femur; a sinus above Poupart's ligament is usually denotive of disease of the ramus of the pubes, and one in the perineum of disease of the ischium. To these rules, of course, occasional exceptions occur. In the examinations of these sinuses a vertebrated or articulated probe will be of great service, as it can be made to follow their sinuosities much more readily than a straight instrument.

Valuable information as it respects the extent of the ravages produced in hip-joint disease may occasionally be obtained by digital explorations of the rectum, or the rectum and vagina. Such examinations are particularly demanded when the existence of pelvic abscess is suspected, or when there is serious disorganization of the iliac bone and its periosteum, or great involvement of the pelvic lymphatic glands. The use of chloroform will often be of great service in conducting the movements of the limb while the patient is recumbent, especially when the parts are very painful and intolerant of manipulation.

Morbid Anatomy.—The anatomical changes which occur in coxalgia are essentially similar to those witnessed in strumous affections of the joints generally. They are usually more conspicuous, in every stage of the malady, in the head and neck of the femur than in the innominate bone, which, however, often suffers very severely during the progress of the morbid action.

When the disease has attained its acme, the synovial membrane, the round ligament, the articular cartilages, and the head and neck of the thigh-bone, with the margins, and frequently, also, the bottom of the acetabulum, are partially destroyed, if not completely annihilated. In the more severe cases the cotyloid, transverse, and even the capsular ligament are entirely absorbed, the surrounding parts are extensively separated by the ulcerative and suppurative processes, numerous fistulous openings exist, and the gluteal muscles are transformed into dense, firm bodies, of a pale-reddish, yellowish, or whitish color. Sometimes, especially when the disease is of long standing, these muscles undergo the fatty degeneration. Occasionally both trochanters are absorbed; or there is extensive caries of the innominate bone; or the head and neck of the thigh-bone are necrosed; or the joint contains numerous fragments of bone and cartilage; or, the bottom of the acetabulum being perforated, the matter extends into the pelvis, and passes off by the rectum. In children, prior to the completion of the ossific process, the hip-bone is sometimes separated, at the acetabulum, into its three primitive pieces; and epiphyseal sequesters of the head and neck of the femur are also occasional occurrences.

When the head and neck of the femur are absorbed, the remnant of its superior ex-

tremity usually lies across the acetabulum, or in its immediate vicinity. Occasionally it is drawn up a little beyond this cavity, against the surface of the ilium, resting in a slight depression, which, however, bears only a very faint resemblance to a new socket. Instances have been observed in which it was forced backwards into the sciatic notch, forwards upon the pubic bone, or downwards into the thyroid foramen. When the disease has expended itself mainly upon the acetabulum, the head of the thigh-bone may retain its original position, or it may even be pushed into the pelvic cavity. The ravages produced by this disease, in its earlier stages, in the acetabulum and the head and neck of the femur, are well illustrated in the annexed cut, fig. 612.

Fig. 612.

Changes wrought in the Acetabulum and Head of the Thigh-bone in Coxalgia.

An examination of the bodies of those who die from the effects of coxalgia always reveals important lesions of some of the internal organs. In 1858, I published an elaborate paper upon tuberculosis of the hip-joint, accompanied by an account of the post-mortem appearance of five cases, the ages of which were, respectively, nine, ten, twelve, twenty-three, and twenty-six years, in every one of which there were numerous tubercles in the lungs, either in a crude, softened, or ulcerated condition. The spleen, in three of the cases, was crowded with tubercles, and in nearly all tubercles were present in the pelvic and mesenteric glands. The liver was similarly affected in one of the cases, the kidneys in two, and the bronchial lymphatic glands in one. The peritoneum, in one of the cases, was studded with tubercles, and its cavity contained three quarts of serous fluid. These cases, so far as they go, clearly prove the connection of coxalgia with a strumous state of the system, either as cause or effect. Amyloid degeneration of the kidneys is not infrequent in the more advanced stages of the disease, and, together with tubercular meningitis, is a considerable source of its mortality. Many children perish from mere exhaustion, worn out by profuse suppuration, loss of appetite, night sweats, and hectic irritation.

No one who has studied the pathology of this disease can doubt its tubercular character. The researches of Billroth, Koenig, Bidder, Volkmann, and other German investigators clearly point to this conclusion; and similar evidence is afforded by the elaborate statistics of Dr. Gibney, showing as they do a large percentage of hereditary influences. Many American, English, and French surgeons are converts to this doctrine, and it may safely be predicted that the time is rapidly approaching when this belief will become general, if not universal. The fact that external injury often acts as an exciting cause of the disease does in no wise invalidate the truth of this opinion. Traumatism, in any case, is simply an exciting cause, and nothing more: wholly inoperative when there is no local or constitutional vice or predisposition. "It is impossible for a physician," says Gibney, "to be long connected with a dispensary or hospital in a large city without coming to the conclusion that some vice, either hereditary or acquired, must underlie the constitutions of the vast majority of the poor who lack medical assistance." For some recent views upon this subject, the reader may with advantage consult a paper by Mr. John Croft, of St. Thomas's Hospital, in the Transactions of the Pathological Society of London for 1881.

Prognosis.—As there are no mortuary statistics of this affection, it is impossible to state, with any degree of precision, the mean duration of fatal cases, or the relative proportion of deaths to recoveries. My opinion, founded upon numerous observations, is that the mortality from coxalgia is slight in almost any event, even when there has been palpable neglect in regard to its treatment. The prognosis is generally most unfavorable in feeble, anemic children, with a tumid upper lip and a protuberant abdomen, the offspring of strumous parents, or of persons whose system is thoroughly impregnated with the syphilitic poison. Young adults seldom ever recover, if suppuration occur; the whole system soon becomes involved in the disease, and they rapidly sink under the profuse discharge and hectic irritation. Few children die before the eighteenth month. The case is always more likely to terminate unfavorably when the disease involves the acetabulum, or the acetabulum and the surrounding osseous tissue, than when it is limited to the head and neck of the femur. Primary disease of the acetabulum is also a much more serious

occurrence than secondary disease, or disease consequent upon disease of the thigh-bone. Under the present improved mode of treatment, more lives are saved than formerly, as well as more useful limbs retained. If the disease has been neglected, and recovery occurs, the individual will be permanently deformed and crippled, and a long time will elapse before he will be able to regain his health. The hip is often completely ankylosed without the previous formation of an abscess.

The angle which the limb forms with the body in cases of recovery, varies, according to Gibney, from 90°, as the minimum, to 150°, 160°, or even 170°, as the maximum. The shortening is generally very slight when there is no serious structural change in the articular surfaces; when the reverse is the case, and especially when there is great destruction of the head and neck of the thigh-bone, the shortening may amount to two, two and a half, three, and even four inches. The disease sometimes lasts for many years, and yet the patient may finally recover, enjoying, perhaps, tolerably fair health during the remainder of his life.

Treatment.—Although the treatment of coxalgia involves the same principles as that of tuberculosis of the joints in general, there are certain points to which it is necessary to direct special attention, growing out of the peculiar structure and situation of the articulation, the frequency with which it is assailed by this disease, and the tender age of those who are most obnoxious to its attacks.

Rest of the affected joint, as well as of the whole body, is of primary importance, and should be attended to without delay. The restraint must not be limited to a few days or weeks, but be continued so long as there is the slightest evidence of active disease. In order to render the patient as comfortable as possible, and enable him to endure his protracted confinement without detriment or inconvenience, a suitable bed provided with slats and a firm but elastic mattress must be secured. A common trundle-bed, about four feet in width, will answer every purpose, and is, in every respect, preferable to the common bed, especially if the patient be a child, as he will thus be less liable, if he should roll out, to hurt himself. The sheet should be well fastened at the sides, that it may not become rumpled, and the pillow should be very thin, so that, while it affords adequate support to the head and shoulders, no undue weight may be thrown upon the trunk and pelvis. The confinement, however rigid, will not prove irksome; with the aid of toys and other sources of amusement the little patient will generally in a few days become reconciled to this new mode of life.

With strict attention to this point, the disease, if in its incipiency, may generally be easily arrested without any formal treatment, excepting, perhaps, the occasional exhibition of a laxative and a proper regulation of the diet. If the joint is stiff, and painful on pressure, a few leeches may be applied, or the skin may be thoroughly painted once a day with dilute tincture of iodine, or a small blister may be raised, and the raw surface sprinkled with morphia. A diaphoretic and anodyne draught may, if fever exist, be administered at bedtime. The best laxative, in this stage of the disease, is calomel, in doses of one to two grains with twice that quantity of jalap. The diet must be very plain and simple, especially if the patient be, in other respects, well conditioned. General bleeding will seldom be required, unless the suffering is extremely severe and the blood decidedly thick and abundant, when the loss of a few ounces cannot fail to be highly beneficial.

To control the spasmodic action of the muscles, and thus afford more perfect repose to the diseased joint, the limb should be confined by a splint, extending from near the crest of the ilium to within a short distance of the ankle, and so constructed as to cover in nearly the whole of the affected buttock. The most suitable materials are wire gauze, gutta-percha, undressed sole-leather, or trunk-maker's board, soaked in hot water, carefully moulded to the hip, thigh, and leg, and kept in place with adhesive plaster and a common roller. When dry, these substances form an admirable case, which, if properly padded, effectually wards off pressure and prevents excoriation. To render any contrivance of this kind thoroughly efficient by placing the affected joint in a state of perfect repose, beyond the spasmodic action of the muscles of the thigh, extension and counter-extension must for some time be steadily maintained in the same manner as in the treatment of fractures of the lower extremity, that is by adhesive plaster, pulley and weight, and by elevation of the foot of the bed. The weight should vary according to the age of the patient, from two to four, six, or eight pounds, its effect being carefully watched, otherwise it may give rise to great discomfort, if not serious detriment. Dr. Physick, who was the first to insist upon the necessity of absolute rest in the treatment of coxalgia, used a splint of carved

Fig. 613.
Sayre's Apparatus.

wood, very light, well padded, and carefully adapted to the size and shape of the hip and limb. When the patient is in a condition to exercise in the open air, there is no apparatus that answers so good a purpose for securing quietude to the affected joint as that of Dr. Sayre, or one that can be used with greater ease and comfort. It consists, as seen in fig. 613, of two pieces of corrugated steel, the lower of which is made to slide within the upper by means of a key, thereby forming a splint which extends from the crest of the ilium to two inches above the condyles of the femur. To the upper end of the splint is attached, by means of a ball and socket joint, a padded, concave steel plate, which rests upon the pelvis just below the crest of the ilium, and to each extremity of which the perineal band, made of buckskin, stuffed with hair, and terminating in elastic webbing, is secured by buckles. At the lower end of the splint are a roller and buckle intended to receive a webbing stitched to the retaining adhesive plaster, while two semicircular steel bands pass from this portion across the front of the thigh to another straight piece which rests on the inner side of the limb, parallel with the outer bar, and also terminates in a roller and buckle. A strap which extends posteriorly from the inner to the outer rod, is intended to secure this portion of the apparatus when it is adjusted.

To apply the instrument, two fan-shaped pieces of strong, inelastic adhesive plaster, with webbing sewed on to their narrow ends, are required, long enough to reach from the perineum to within two inches of the inner condyle and from the great trochanter to a similar point on the outer side of the limb. These having been secured by a roller, the splint is laid over the thigh, and the webbing, attached to the plaster, fastened over the rollers to the buckles on its lower end, the traction being completed by securing the posterior strap. The perineal band is then buckled on, and extension is made with the key, to such a degree as to render the patient comfortable. With the assistance of a crutch, he may, with this contrivance, exercise during the day in the open air, while at night, as he lies in bed, the requisite degree of extension may readily be effected by means of a pulley, cord, and weight, attached to the limb in the usual manner. In connection with exercise in the open air, I may mention, with special emphasis the ingenious method of treatment recommended by Dr. Joseph C. Hutchison, of Brooklyn, and now much employed in this, if not also in other countries.

Fig. 614.

It simply consists in removing the weight of the body from the affected limb to the sound one by means of an elevated shoe and a pair of crutches as seen in figs. 615 and 616. By this very simple arrangement the affected limb is suspended during progression and maintained in an easy and relaxed position. At night extension may be applied or not, according to the absence or presence of muscular spasm. Dr. Hutchison's shoe is the one ordinarily used for shortened legs provided with a steel plate corresponding to the sole, to which it is attached by two upright rods from two and a half to three inches in length, so as to raise the foot from the ground. In order to avoid vicious position and keep the joint thoroughly at rest, this treatment should be supplemented by the application of the posterior splint of Thomas, represented in fig. 617. The only objection to this contrivance is that it renders sitting very awkward, to obviate which Dr. Willard has devised the admirable apparatus, depicted in fig. 618, which is particularly adapted to the earlier stages and milder forms of the disease, where gentle motion is permissible, and ankylosis is to be prevented. It is made of perforated leather, and consists of two pieces, one corresponding with the thigh, and the other with the hip and pelvis, connected by a hinge-like joint, which may be hooked or unhooked at pleasure. It is accurately moulded to the surface, and is laced down in front of the thigh and abdomen.

In the *second stage* of the affection, the great topical remedy is an issue made with the actual cautery, applied to the most prominent part of the swelling, or as nearly as possible to the focus of the morbid action. The eschar, which should be from half an inch to an inch in diameter, usually drops off in six to eight days; the sore, besides furnishing an ample supply of thick pus, affords an excellent surface for the endermic use of morphia,

now so necessary for allaying the violent pains and spasmodic twitchings of the muscles. If the discharge flag, it can easily be reëxcited with some stimulating unguent. It should

Fig. 615.

Fig. 617.

Hutchison's Shoe.

Hutchison's Shoe Applied.

Thomas's Posterior Splint.

be maintained in full force until the severity of the disease has completely subsided. The quantity of morphia necessary to compose the parts and system is, according to the age and other circumstances of the patient, from a quarter to a third of a grain sprinkled upon the surface of the issue once or twice a day. If the general health suffer from want of exercise, the limb may be put up in a suitable apparatus, and the child sent into the open air.

The violent contraction of the muscles, so common in this stage of the complaint, and a source of so much pain and distortion, may generally be promptly relieved by the use of the tenotome. The muscles that are most frequently at fault are, the sartorius, pectineal, and short adductor, which, if they do not yield under the influence of chloroform, should be thoroughly divided near their origin, until all resistance to the extension of the limb is overcome.

In the *third stage* of the disease, when abscesses exist in and around the joint, accompanied by hectic irritation, the indications plainly are to evacuate the matter and to support the system. The knife should be introduced in such a manner as to make a valvular incision, as in an ordinary strumous collection, the opening being immediately closed with adhesive plaster, and the operation repeated at intervals of six, eight, or ten days, until all tendency to reaccumulation has disappeared. The object should be, while affording free discharge to the pent-up fluid, to permit as little air to penetrate the joint as possible. Undue reaction must be prevented by full and sustained doses of opium until the part and system have accommodated themselves to their new relations. Quinine and iron, cod-liver oil, beef essence, milk punch, and elixir of vitriol will afford material aid in maintaining the

Fig. 618.

Willard's Splint.

strength at this trying juncture. Any dead bone that may exist must for obvious reasons at once be removed. When the pus has been evacuated, the affected parts should be supported with some sorbefacient and slightly stimulating plaster, as the soap, galbanum, or ammoniac and mercurial, the latter being the best. The sinuses about the joint may be injected with a weak solution of iodine, iodide of iron, nitrate of silver, bichloride of mercury, permanganate of potassium, or chlorinated sodium. If numerous, and not too deep, they may often be advantageously laid open, provided it can be done without pain and the loss of blood. As soon as the patient is able, he should exercise in the open air; and the affected joint should be moved to prevent ankylosis.

When the parts in and around the joint are so much diseased as to render recovery by the ordinary means entirely hopeless, the only thing that remains to be done is excision. The operation, the statistics of which will be given in a future chapter, may be conveniently performed by making a curvilinear incision, from four to five inches in length, perpendicularly over the joint, in a line with the great trochanter, separating the parts, and cutting off the diseased structures with the saw or pliers. If more room be required, the incision may be crucial, or in the form of a T or V. The flaps are afterwards approximated with stitches and adhesive strips, and the immobility of the limb is secured by appropriate splints, pads, and bandages, as in fracture of the thigh-bone.

Important information on the comparative value of the expectant plan of treatment and excision in disease of the hip-joint has recently been published by a committee of the Clinical Society of London. Of 384 cases treated by prolonged rest, extension by weights, and opening abscesses, 100, or 26 per cent., died, 87 of the deaths having occurred in 260 of the cases in which suppuration was present: 196 of the patients were reported as cured or as convalescing, while in 88 the disease was still in progress. Of the 260 cases in which suppuration had taken place, 33.5 per cent. died, while of 45 cases of excision performed by Mr. Croft, 40 per cent. were fatal. In favor of excision, however, it may be said that the movements of the limb are more frequently retained, as well as more extensive, than when the expectant plan is pursued; on the other hand, however, the limb is less firm and less useful for the purpose of progression.

When, as occasionally happens, a sequester exists in the neck of the femur, whether as the result of actual necrosis, or of epiphyseal disjunction, excision should give way to the ordinary operation for the removal of dead bone. Such an occurrence is by no means infrequent, and the surgeon should, therefore, spare no pains to ascertain the true condition of the parts before he adopts so severe a measure as excision.

When the acetabulum is involved in the disease, it should be dealt with in the same manner as the femur, every particle of morbid structure being removed with the pliers, gouge, chisel, and scraper. With proper care, there will be no danger whatever of injuring any of the contents of the pelvis, inasmuch as the periosteum and connective tissue are always so greatly indurated and thickened during the progress of the disease as to serve as a strong wall of defence. When, as is sometimes the case, after such an operation, the blood oozes from numerous points, a prompt and effectual stop may usually be put to the flow by means of hot water or of Monsel's salt, applied upon wet cotton.

When the patient has been exhausted by protracted suffering, and life is fast ebbing away, it has been proposed, as a dernier resort, to amputate at the hip-joint; and the records of surgery contain several examples in which the operation was performed successfully. I should, nevertheless, hesitate before undertaking so grave a procedure, the more especially as the same end may generally be more readily attained by the more simple and less dangerous operation of excision. It is only, indeed in cases of great disorganization, deformity, or wasting of the limb, rendering it utterly useless as an organ of progression, or interfering more or less seriously with the ordinary movements of the body that, in my opinion, amputation should be preferred to excision of the head, or head and neck of the femur.

The deformity of the limb and pelvis, consequent upon the disease, may often be very materially relieved, if not completely removed, after the morbid action has measurably subsided, by careful extension and counterextension of the limb, by means of a weight and pulley, conjoined with passive motion, and the use of suitable apparatus when the patient begins to exercise in the open air. One of the best contrivances for this purpose is that depicted in the adjoining cut, fig. 619, one of the many ingenious inventions of the late Professor Pancoast. In fig. 620, the apparatus, which should always be as light as is consistent with strength and durability, is exhibited as applied to the patient. It is of course laid aside at night, and before it is readjusted in the morning, the limb should

always be well washed and rubbed. It is hardly necessary to add that the exercise should be as gentle as possible, that it should be taken with the aid of a crutch, and that it should never be carried to fatigue. The disease which too often slumbers may be easily reawakened, if these precautions be not rigidly enforced.

Fig. 619.

Fig. 620.

Pancoast's Apparatus for Coxalgia.
Splint Applied.

The adhesions of the joint and of the surrounding structures are most easily broken up with the aid of an anæsthetic. Unless great attention be bestowed upon the case for a long time after the active disease has vanished, great and irremediable deformity will be inevitable.

Much, if not irreparable, injury is often inflicted upon the part and system by injudicious passive motion in the treatment of coxalgia. It is only, or mainly, in the earlier stages of the disease that such efforts will be at all likely to prove beneficial. When the joint has undergone serious structural changes, as when the disease is well advanced in its second stage, in which there is always more or less destruction of the synovial membrane, if, indeed, not also of the articular cartilages, the only rational thing to be done is to place the corresponding limb in the best position for future usefulness, and to favor the occurrence of ankylosis instead of adopting measures to prevent it. The altered structures in such a condition cannot possibly be reclaimed by any skill, however great or well directed, of the surgeon, and hence any attempts that may be made with a view of reëstablishing motion must inevitably end in failure, if not, in what is much worse, in the rekindling of morbid action. It is, as it were, taking the case out of nature's hands, and thwarting her efforts at a cure by rendering the affected joint permanently motionless. In the propriety of this advice all surgeons of experience will, I am sure, concur.

SECT. VIII.—CHRONIC RHEUMATIC ARTHRITIS.

The joints are liable to a peculiar form of disease, known under the name of chronic articular rheumatism, or chronic rheumatic arthritis, first systematically described by Dr. R. W. Smith and Dr. R. Adams, of Dublin, the latter of whom has published an able and elaborate treatise upon it. It occurs in both sexes, chiefly in elderly and middle-aged subjects among the laboring classes, although it is also occasionally observed in the

higher orders of society, especially in the indolent and habitually intemperate in eating and drinking. The joints most prone to suffer are those of the hip, knee, wrist, and fingers, one of which only may be affected, or a number may be implicated simultaneously, or in more or less rapid succession. Sometimes the disease leaves one articulation, and fastens itself upon another; but, in general, when it has once effected a firm lodgment it holds on to it pertinaciously, now and then remitting, but seldom entirely intermitting, at least not for any length of time. Ill-fed and ill-clothed persons, living in moist, under-ground apartments, or in damp, confined alleys, are particularly liable to it. A gouty or rheumatic predisposition probably favors its outbreak.

The immediate cause of the disease is generally suppression of the cutaneous perspiration from exposure to cold, or from long-continued immersion of the feet in water, as often happens in the laboring classes. Occasionally its origin is traceable to external injury, as a blow, sprain, or concussion. In the female it is sometimes apparently dependent upon irregularity of the menses; and in both sexes it is frequently connected with dis-order of the digestive apparatus, as dyspepsia, constipation, or derangement of the biliary secretion.

The disease often, if not ordinarily, approaches in a slow and stealthy manner, the first symptoms being usually merely a sense of soreness and stiffness of the affected joint, with slight derangement of the general health. As it progresses, the local distress assumes a more marked and open character; what was before only a feeling of uneasiness now becomes a source of real pain and distress. The joint gradually growing rigid, moves with great difficulty, and a careful examination seldom fails to detect fluctuation, dependent upon the presence of synovial fluid, an early product, and generally the principal one, of inflammation in its milder forms. When the effusion is considerable, it will necessarily seriously change the contour of the affected joint, the synovial membrane bagging across the ligaments, as is so apt to happen when the disease is seated in the knee, wrist, or elbow. It is seldom that pus forms in any case, even if unusually severe and protracted; but plastic matter is often poured out in large quantity, and it is the presence of this substance that causes the remarkable rigidity which so constantly attends the com-plaint in its more severe grades. Spasmodic twitchings of the muscles in the neighbor-hood of the affected joint commonly set in at an early period of the inflammation, and constitute a source of great distress, effectually interrupting sleep, and requiring large doses of anodynes for their relief.

The pain in chronic rheumatic arthritis is often excessive; it is always increased by motion and pressure, and is usually materially aggravated at night. It is of a dull, heavy, aching character, and frequently extends in different directions, but especially along the course of the larger nerves, which it sometimes follows to their very extremities. The general health suffers severely; the patient is feverish, and deprived of appetite and sleep; the bowels are constipated; and the skin is hot and arid. The urine, however, although commonly scanty and high-colored, does not deposit any lithic acid, a circum-stance which remarkably distinguishes this disease from gout and rheumatism, properly so called.

In old cases of this disease, or in the strictly chronic form of it, the general health, although perhaps somewhat impaired, is comparatively good, and the patient may even grow fleshy and ruddy. His locomotive powers, however, are greatly deranged, and he is, in consequence, often obliged to use crutches. The affected joints are habitually ten-der, sore, and distorted, not unfrequently presenting an appearance of being partially dislo-cated. Such a change is particularly liable to occur in the fingers, but is also occasionally noticed in the hip, shoulder, and other large articulations. Exostoses sometimes spring from the sides of the affected joints and serve to add to the deformity, already sufficiently great. The synovial burses are also apt to suffer, becoming inflamed, enlarged, and dis-tended with fluid. The muscles, in consequence of their perpetual inactivity, become atrophied and powerless. What strikes the observer as very peculiar, amidst these changes, is the entire absence of cretaceous deposits in and around the disabled joints.

Chronic rheumatic arthritis is essentially an inflammatory malady. The affected struc-tures, if examined in the earlier stages of the disease, will be found to exhibit indubitable evidence of vascular injection of the synovial membrane, and of the presence of synovial fluid, with here and there, perhaps, a patch of lymph, or more or less of this substance intermingled with the other secretion. Pus, as already stated, is seldom seen. When the disease is permitted to go on unchecked, great structural changes gradually take place, consisting in the removal, either partial or entire, of the synovial membrane and articular cartilages, and the conversion of the extremities of the bones into a hard, ivory, or por-

cellaneous substance, totally destitute of its normal qualities. In many cases the ends of the bones have a beautiful polished aspect, being perfectly smooth and glistening; while in others they are remarkably rough and tuberculated, or beset with exostosic incrustations. The interarticular fibro-cartilages are generally completely destroyed, and the funicular ligaments often undergo partial absorption, while the capsular are liable to become stretched and relaxed, thus allowing the bones to slip away from each other, and produce an appearance of partial dislocation. Finally, fibroid, fibro-cartilaginous, and osseous growths, of various shapes and sizes, are extremely prone to form in the interior of joints thus affected.

What is the pathology of this disease? That it is of an inflammatory nature, is unquestionable; but how it is produced, or what the peculiar condition of the system is which predisposes to its development, or which keeps the affection in play after it has been fairly established, are circumstances in its history of which we are totally ignorant.

The diagnosis is commonly very easy, especially in the more chronic forms of the disease. The history of the case, the excessive obstinacy of the disease, and the gradual failure of the functions of the affected joint, together with its distorted appearance, and the absence of cretaceous deposits in the structures around the articulation, and of lithic acid in the urine, always readily distinguish it from ordinary gout and rheumatism, the only maladies with which it is at all liable to be confounded.

The prognosis is generally most unfavorable. In the milder forms of the disease, and in its earlier stages, a cure is certainly occasionally practicable, but under opposite circumstances the patient almost invariably remains a cripple for life, as it is impossible by any mode of treatment at present known to effect restoration of the disorganized structures of the affected joints.

Treatment.—In the treatment of this affection, everything depends upon the efficiency with which the case is met in its earlier stages; for, after the morbid action has made serious inroads, all that can, in general, be expected from remedial interference is a mitigation of suffering, seldom anything like a complete, permanent cure. Unfortunately it but too often happens that the disease has occasioned great disorganization of the affected structures before the practitioner is afforded an opportunity of taking it in hand. Considering its inflammatory character, the course of treatment to be adopted is indisputably the antiphlogistic, directed not to the part merely, but also, and in an especial manner, to the state of the general system, which, whatever may be the real pathology of the disorder, is always more or less extensively implicated. In this country there are few cases of chronic rheumatic arthritis which will not, in their earlier stages, bear active depletion by the lancet, purgatives, diaphoretics, and antimonials. The quantity of blood taken from the arm must, of course, depend strictly upon the condition of the constitution, as to the existence or absence of plethora, anorexia, and other evidence of vascular disturbance. Mercurial purgatives administered in efficient doses, in union with jalap or rhubarb, and compound extract of colocynth, are among the most reliable means that can be employed for arresting the morbid action; and it would be difficult to conceive of any case in which they can altogether be dispensed with. At the same time, however, they must be used with caution. The improvement of the secretions always forms an important indication, and there is no class of remedies so likely to do this promptly and effectually as purgatives. After the violence of the disease has been moderated by these means, the most efficient prescription, according to my observation, is a combination of morphia, antimony, and veratrum viride, given in full and sustained doses, until it makes its specific impression upon the heart and nervous system. Half a grain of morphia, with one-sixth of a grain of tartar emetic, and ten drops of tincture of veratrum viride, is a fair average quantity for an adult, to be repeated once or twice in the twenty-four hours, according to the severity of the suffering, or the effects of the remedy, which should, of course, always be carefully watched. Administered in this way, it promptly subdues pain, produces perspiration, and reduces vascular excitement. When this result has been brought about, the medicines are given in smaller or less frequently repeated doses, until the necessity for their exhibition entirely ceases.

Colchicum is seldom of any material benefit in this disease in any of its stages; for, although the disorder unquestionably generally partakes of a rheumatic or gouty nature, yet, as already stated, there is rarely any lithic acid deposit in the urine, or cretaceous formation within the joints, and this is probably one, if not the principal, reason of the inefficiency of the medicine. Dover's powder may occasionally be employed with great benefit; and salicin is also worthy of trial.

Among the more important topical remedies are leeches and fomentations, medicated

with acetate of lead, opium, and aconite. Local steam baths are sometimes highly beneficial, the vapor being conducted by means of a tube to the inflamed parts. Cold applications are rarely admissible, from their tendency to shock the system and to cause metastasis. As the disease declines, dilute tincture of iodine and steady, systematic compression with the bandage will be found serviceable; and, at a still later period, passive motion may be instituted, the parts around the joint being at the same time well douched and shampooed, to promote the absorption of effused fluids and the restoration of impaired function.

In the more advanced chronic forms of the affections the main reliance of the practitioner must be upon a proper regulation of the diet, which must be chiefly of a mild, farinaceous character, with a little white meat or fish at dinner; the preservation of the secretions by the occasional exhibition of a few grains of blue mass, or calomel; the steady, persistent use of iodide of iron, either alone or in union with iodide of potassium; and a residence in a dry, genial climate, exempt from sudden and severe vicissitudes. A sojourn for several months at the Hot Springs of Arkansas, with the daily use of the warm baths obtainable at that place, often proves serviceable. If the general health is much broken, cod-liver oil with iron and quinine may be required, the body being incased in flannel, and gentle exercise taken in the open air, to prevent ankylosis, which is always so much favored by inactivity in all articular affections, of whatever character.

When the disease is followed by permanent ankylosis, an attempt may be made to place the corresponding limb in proper position by separating the ends of the bones by means of the perforator and chisel, as advised in the section on ankylosis; or, if the case do not admit of such interference, excision might be practised, as was done, although unsuccessfully, in an instance of this kind, by Ridewald, in 1770. His patient, a man of fifty years old, was in bad health at the time, and died from the conjoint effects of suppuration and hemorrhage after amputation, performed as a dernier resort. I am not aware that an operation for such an object has been employed by any other surgeon, and yet it is easy to perceive that cases might arise rendering a resort to the knife highly proper.

CHRONIC RHEUMATIC ARTHRITIS OF PARTICULAR JOINTS.

Although this disease may, as already stated, occur in any of the joints, it is by far most frequent in those of the carpus and fingers, where it is always readily recognized by the pain, stiffness, and permanent distortion which it occasions. The elbow, wrist, and ankle-joints rarely suffer from it. When the malady is constitutional, the sterno-clavicular and acromio-clavicular articulations are liable to be invaded, and it then often requires more than ordinary care and skill to determine the diagnosis, especially if the parts have recently been subjected to local injury, as a blow or fall, thus exciting doubt as to whether the affection is one of rheumatism, dislocation, or fracture. In a practical point of view, however, it is chiefly in the lower jaw, spine, elbow, hip, and knee that the disease is of much interest.

Chronic Rheumatic Arthritis of the Lower Jaw.—In the lower jaw the disease is frequently symmetrical, although it rarely exists in an equal degree on both sides. The subjects are usually elderly men, after the fiftieth year, who have been exposed to all kinds of hardships. Among the earlier symptoms is a slight degree of stiffness in the joint, which is soon succeeded by pain, and by a creaking, crackling, or grating sensation, particularly annoying during eating, and often so loud as to be heard at some distance. The cause of this sensation is evidently an absence of synovial fluid. The condyloid process increases in size, and forms a distinct knob in front of the ear. The mouth is opened with difficulty, mastication is greatly restricted, and the chin and face are distorted from the destruction of the articular eminences, allowing the external pterygoid muscles to drag the bone out of its natural position. When both joints are affected the chin is elongated, but if only one suffers the jaw is thrown towards the opposite side, very much as in a traumatic unilocular dislocation. The pain is generally worse at night than in the day, as well as in damp than in dry weather, and there is often considerable enlargement of the lymphatic glands of the upper part of the neck. The fibro-cartilage is destroyed; the surfaces of the joint, divested of their natural coverings, are of a porcellaneous hardness; the articular eminences are flattened, if not entirely wasted; and the condyles are enlarged and disfigured.

The diagnosis is determined principally by the age of the patient, the gradual changes in the joint, face, and chin, and the symmetrical character of the attack.

Chronic Rheumatic Arthritis of the Spine.—This disease occasionally invades the spine, especially the cervical and dorsal divisions ; the subjects are generally elderly persons, and the attack is commonly associated with the same affection in other regions of the body. The most distressing forms of the disease are met with in the lower part of the neck and the upper part of the back, where it often causes great deformity, the curvature being a combination of the posterior and lateral varieties. The trunk, in time, becomes greatly arched, and the patient is unable to stand erect, or to turn his head from side to side. The earlier symptoms are, gradually increasing pain and stiffness, and a crackling noise heard on motion of the affected joints.

The diagnosis rests upon the history of the case, as the age of the patient, the absence of local tenderness, or, what is tantamount to this, the tolerance of the parts under rough manipulation, and the fact that the patient does not experience any marked pain if the spine be forcibly concussed through the skull as he sits upon his chair.

Chronic Rheumatic Arthritis of the Shoulder.—When this disease attacks the shoulder, it may come on either as an independent affection, as when it is caused by external violence, or, as is more generally the case, it coexists with chronic arthritis of some of the other articulations. The earlier symptoms are, stiffness of the joint, with a crackling sensation on moving the arm, a deficiency of synovial fluid, more or less pain, especially at night, and in damp states of the atmosphere, and gradual wasting of the deltoid muscle. As the disease proceeds, the joint becomes more and more rigid, from the dryness of its surfaces, and the effects of plastic deposits, the shoulder presents a wasted appearance, the acromion and coracoid processes stand out in bold relief, and the movements of the arm are restricted within the most narrow limits. The patient can still abduct the limb slightly, but he finds it impossible to elevate it to a horizontal level, or to carry it behind the trunk. The head of the humerus is generally a little raised, as well as somewhat nearer the middle line than natural, the scapula is unusually mobile, and a remarkable depression exists at the posterior part of the joint.

The diagnosis is established by the history of the case. When the disease is constitutional, its coexistence with similar attacks in other joints is sufficiently denotive of its character. When it is caused by injury, it may be confounded with tuberculosis, from which, however, it may readily be distinguished by the crackling sound that attends the movements of the arm, and by the fact that the parts are much more tolerant of pressure and rude manipulation. In caries of the joint the slightest motion is productive of intense pain, there is more swelling, with greater constitutional disturbance, and the affected structures ultimately run into suppuration, an effect which is never witnessed in chronic rheumatic arthritis.

When a person, affected with this disease, is so unfortunate as to meet with a fall or blow upon the shoulder, the surgeon may find it very difficult, if not impossible, unless he is fully acquainted with the previous history of the case, to determine whether the affection is one merely of sprain, fracture, or dislocation.

The head of the humerus, partly absorbed, flattened, and nodulated, is denuded of cartilage at one place, porous at another, and eburnized at a third. In very old cases it generally rests against the under surface of the acromion and coracoid processes, in a kind of socket formed for its accommodation. These processes themselves are often greatly changed ; sometimes they are much enlarged and roughened, at other times completely wasted. The glenoid cavity is expanded and excavated, while its margin is elevated into a sharp, irregular ridge. Sometimes all these parts are soldered together by osseous matter.

The soft structures around the joint are materially altered, the muscles are pale, wasted, and flabby, the long head of the biceps is destroyed, the tendons have a macerated appearance, as if their fibres were separated into their original elements, and the capsular ligament is thickened and perforated, or hypertrophied at one point and atrophied at another.

Chronic Rheumatic Arthritis of the Hip.—This affection is nearly always met with in elderly persons laboring under the rheumatic diathesis. For this reason it frequently coexists with the same disease in other parts of the body. Sometimes, however, it is limited to one of the hip-joints, and is then generally caused either by external violence, or by suppression of the cutaneous perspiration. Falls and blows upon the great trochanter occasionally give rise to it. Males are by far its most frequent subjects.

The earliest evidence of the disease is a stiffness in the joint, which is generally most annoying in the morning when the patient gets out of bed, but which gradually diminishes after exercise, provided this is not carried to severe fatigue, which always produces an opposite effect. At first there is little or no pain, but after a while this becomes a prominent and distressing symptom. It is either dull and aching or of a gnawing or boring

character, and is most severe in the joint and in the great trochanter, from which, however, it radiates in different directions, as up into the gluteal region and down along the thigh, often as far as the knee and even the leg. It is increased by motion and exercise, is worse at night than in the daytime, and is influenced by the state of the atmosphere. The patient walks very lame, and, as he supports the weight of his body upon the sound limb, the affected one is drawn up in such a manner as to give it a shortened appearance. The foot is strongly everted, the power of rotation is lost, the buttock is flattened, the gluteo-femoral crease is effaced, the muscles of the thigh are attenuated, and a crackling sensation is perceived on moving the joint. The patient cannot stoop when he stands, and when he sits he is compelled to stretch out his leg. The trochanter is unusually prominent, and progression is painful and restricted. Great shortening of the limb at length takes place, often amounting, apparently, to two and a half or even to three inches, but, in reality, seldom exceeding one-third of that amount, and depending mainly upon the wasted condition of the head and neck of the thigh-bone.

The principal affections with which this disease is liable to be confounded are tuberculosis and sciatica. From the former it may usually be readily distinguished by the fact that the malady nearly always occurs in elderly subjects, by its frequent coexistence with similar attacks in other parts of the body, by the peculiar crackling sensation produced on moving the joint, by the absence of heat, swelling, and tendency to suppuration, by the greater tolerance of the parts under rude manipulation, by the flattening of the nates, by the remarkable prominence of the trochanter, and by the natural appearance of the calf of the leg. In sciatica the pain is seated in the sacro-lumbar region; it is generally of a neuralgic character, is often very severe at night, and always extends along the outer and posterior part of the thigh. The motions of the hip-joint are unimpaired, and the limb retains its natural length and direction.

The joint, in the confirmed stage of the disease, is greatly changed in its structure. Its surfaces, completely denuded of cartilage, are remarkably altered in their shape, and exhibit a rough, porcellaneous appearance. The head of the femur, especially its tip, is reduced in size, and often worn down to a mere stump. Sometimes it is quite conical. The neck of the bone is shortened, unusually horizontal, and eburnized. The acetabulum is deformed, scooped out, and scabrous at its margin. The round ligament is annihilated, while the capsular is thickened and perforated, partially destroyed or hypertrophied and inlaid with bony matter. The muscles around the joint are thin, pale, and flabby. In very old cases, the articular surfaces are frequently connected together by stalactites and osseous bridges.

The changes wrought in this disease are beautifully illustrated in the annexed cut, fig. 621. The head of the femur is greatly altered in shape, the neck is much shortened, and the whole contour of this portion of the bone is in an abnormal condition. The acetabulum is materially reduced in size, and the brim is very rough and elevated into a high ridge.

Fig. 621.
Effects of Chronic Rheumatic Arthritis of the Hip-joint.

Chronic Rheumatic Arthritis of the Knee.—This disease usually begins as an ordinary attack of synovitis. The pain, at first very slight, gradually increases, and is generally most severe at the inner part of the joint, particularly over the inner condyle. The stiffness progresses until, at length, it amounts almost to complete ankylosis; the knee is deformed, and crackles when moved; the hamstring muscles are rigidly contracted; the leg is strongly everted; and the tibia is partially dislocated from the femur. The patella is often considerably displaced, and foreign bodies, or cartilaginous concretions, may occasionally be detected in the joint.

The diagnosis is based upon the chronicity of the disease, the absence of any tendency to suppuration, the marked eversion of the leg, the dislocated appearance of the

knee, the singular condition of the ligament of the patella, which forms a distinct band in front of the joint, and the tuberculated state of the margins of the patella and of the condyles of the femur.

The disease not unfrequently appears at a very early age. I have repeatedly witnessed it in children, especially in boys, before the fifteenth year, and in one instance as early as the twelfth.

Treatment.—To the treatment of this affection, as it occurs in these different articulations, little is to be added to what has already been said in regard to the subject in general. The most important internal remedies, especially in the earlier stages of the attack, after venesection, are mercurial purgatives and anodyne diaphoretics, followed, in due time, by a regular course of alterants, especially the iodide of potassium. In chronic arthritis of the lower jaw the best local means are leeches and a series of small blisters in front of the ears. When the disease attacks the spine, dorsal recumbency will be necessary, and should be observed for a long time, otherwise horrible deformity may be the result. A similar plan of treatment, in addition to the use of splints, will be required when the disease involves the hip, knee, or ankle. The elbow and forearm should be well supported in a sling, when it affects the shoulder. Passive motion, friction, shampooing, douching, and electricity come in play at a later period of the disease, and sometimes afford marked relief. Contracted tendons, muscles, and aponeuroses are divided with the tenotome. When the case is of long standing, all that can be done is to mitigate suffering.

SECT. IX.—ANKYLOSIS.

Several varieties of this complaint are met with, as the complete and incomplete, in the former of which all motion is annihilated, while in the latter motion still exists, although in a very limited degree. There is another form of stiffness, in which the structures of the joint retain their normal characters, but are prevented from being exercised by disease in the neighboring tissues, a circumstance which has induced the division of ankylosis into true and false, or intraärticular and extraärticular. This classification is not only more philosophical than the other, but is of the greatest practical importance, as it leads to a just appreciation of the etiology of the disorder, and also, as a necessary consequence, to proper therapeutic indications. The terms complete and incomplete refer, in fact, merely to different degrees of the same complaint, and might be very well replaced by the words fibrous and osseous, as more expressive of the true nature of the ankylosis.

1. *Intraärticular Ankylosis.*—Intraärticular ankylosis may be produced by whatever has a tendency to excite inflammation in the synovial membrane of a joint, with a deposit of plastic matter upon its free surface. Hence it may arise from all kinds of external injury, as wounds, sprains, blows, and contusions; the presence of interarticular bodies; luxations, especially neglected ones; and fractures which involve the joints, or are situated in their immediate neighborhood. Gout, rheumatism, syphilis, and struma also act as exciting causes; but of all these causes, as well as others that might be referred to, there are none which so frequently occasion ankylosis, permanent and irremediable, as fractures and dislocations. Protracted disuse powerfully disposes to the occurrence of stiffness of certain articulations, especially those of the fingers, wrist, and elbow. I am aware that the force of this influence has been denied, but certainly not upon just grounds; for experience has shown, and my own observation has repeatedly verified the fact, that this circumstance alone is often capable of producing ankylosis of a very obstinate and intractable character. Such an event need not surprise us if we remember that motion is the appropriate stimulus of an articulation, and that more or less of this is just as necessary to its healthy action as food is to the stomach, light to the eye, or sound to the ear. When motion is suspended for any length of time, the synovial membrane becomes dry and stiff, and, eventually taking on inflammation, pours out plastic matter, which effectually obliterates its cavity and so induces permanent ankylosis, on the principle that when the function of a part is destroyed its structure is essentially changed in its character, if not completely annihilated.

All joints are liable to this variety of ankylosis, but it takes place much more easily in the ginglymoid than in the orbicular, and among the former, it is more frequently witnessed in the knee, elbow, and wrist than in any others. Several joints are sometimes involved in the occurrence, especially when it arises from gout, rheumatism, or syphilis; and instances have been noticed in which nearly every articulation in the body was completely ankylosed, the skeleton forming almost one rigid piece.

In every case of intraärticular ankylosis a series of alterations must necessarily take

place before the loss of function can be complete. The first step always consists in the effusion and organization of plastic matter, and the second in the gradual conversion of this matter, first, into fibrous tissue, then into cartilage, and finally into bone, the latter forming the ultimate link in the morbid chain. A fibrous ankylosis generally terminates, at no distant period, in osseous ankylosis, the change from one to the other being regularly progressive until the process is completed, this being the method which nature adopts to effect a cure when any serious accident befalls a movable articulation.

These adhesions and transformations vary in extent, not less than in structure and consistence. Sometimes they are very limited, a considerable portion of the synovial membrane remaining sound, or being only slightly affected by disease, and then the connection between the opposing surfaces is generally easily broken up, so that ultimately the joint may regain its original functions. In a second series of cases, again, the fibrous or fibroligamentous bands are not only more numerous, but they extend from different points of one articular cartilage to the other, and thus either obliterate the synovial cavity, or, at all events, completely destroy its usefulness. Finally, in a third class of cases, the new tissue becomes the recipient of osseous deposits, which, gradually increasing in quantity, in time usurp the place of the synovial membrane and cartilage, and ultimately solder the ends of the two bones firmly together. Hence, if a section be made of what was once the joint, the areolar and solid structures will be found to be inseparably blended, their

Fig. 622.

junction being no longer indicated by the thin layer of compact substance which originally invested their heads. These changes are well seen in fig. 622, from a specimen in my cabinet. The femur and tibia are firmly united to each other and to the patella, the three forming one solid piece.

Treatment.—The treatment of this variety of ankylosis must vary according to the nature and extent of the tissues upon which it depends, and also, in no inconsiderable degree, upon the character of the articulation. When the case is of recent standing, when the adhesions are weak and of limited extent, and when the joint is not too complicated in its structure, a reasonable hope may be entertained that the new tissues may be broken up, and brought fully under the action of the absorbents, so that, in due time, and with proper diligence, the functions of the joint may be measurably, if not completely, reëstablished. Under opposite circumstances, however, a cure will not only be difficult, but generally impracticable.

Much may be done in most cases of intraärticular ankylosis, in the way of prevention, by the steady and persistent use of sorbefacients and passive motion. The attendant inflammation having been divested of its violence, the plastic deposits must be disposed of before they have an opportunity of becoming firmly organized, and

Osseous Ankylosis of the Knee-joint.

the only way in which this can be effected is by frictions with stimulating lotions, aided by the cold or hot douche, and by rubbing the articular surfaces gently against each other, at first once every forty-eight hours, and then once or twice a day, until all the matter has been absorbed, and the synovial membrane has regained its primitive characters. Much more skill and attention are required in these cases than the surgeon is generally able or willing to bestow, and it unfortunately too frequently happens that their entire management is confided to persons who are wholly ignorant of the manner in which it should be conducted. The consequence is that a great deal of harm is commonly done, which it is impossible subsequently to rectify by any mode of treatment, however carefully carried out. For the most part, indeed, the time for successful interposition has gone by when the case falls into judicious hands.

When, through neglect, mismanagement, or unavoidable circumstances, the movements of the joint have become greatly impaired, or when the case has already attained a certain degree of chronicity, instead of abandoning the patient to his fate, an attempt should be made to break up the adhesions by forcible means, not forgetting, however, that they must, nevertheless, be conducted with a certain degree of gentleness in order to prevent mischief. The patient being thoroughly anæsthetized, the distal portion of the limb is

moved with one hand, while the proximal, or that nearest to the trunk, is firmly steadied with the other, at the same time that it rests upon a smooth, solid surface, so as to afford a better fulcrum for the part to move upon. Thus, when we wish to break up the adhesions in ankylosis of the knee, the thigh is firmly pressed upon the table, while the leg, drawn away from its edge, is alternately flexed and extended to as great a degree as may be compatible with safety. In operating on the elbow a similar procedure is adopted, the arm being the fixed, and the forearm the movable point. Much muscular power is frequently required to conduct these movements, and yet the greatest care must be taken so to distribute this power as not to produce any mischief. Not long ago, in one of my cases at the College Clinic, I was so unfortunate, in attempting to remedy an ankylosed elbow, as to fracture the humerus immediately above the joint, the accident being announced by a loud snap, very different from the crackling noise which attends the severance of fibrous bands. The patient, a woman sixty-five years of age, had dislocated her elbow nearly three months previously, and the bone had no doubt become softened and brittle from an extension of the inflammation. Such an occurrence is not always avoidable; for I am very sure that in the case in question much less force was used than I had often employed on similar occasions without any such mishap.

The amount of force and the length of time during which it should be continued must vary according to the circumstances of the case, especially the strength and extent of the adhesions. The efforts should always be very gentle at first, and gradually increased as the parts are found to yield. If the joint be tender, it may be necessary to spend a few days in preliminary treatment, as dieting, purging, and, perhaps, even bleeding. The subsequent managment must be of a strictly antiphlogistic character, and the repetition of the operation must depend upon the effects of the first trial; at all events, it should now be conducted with great gentleness, and rather with a view to a passive than an active result. In many cases it will be found advantageous, after the first efforts, to extend the joint by an angular splint, worked by a screw, and worn steadily until the object is attained, the degree of tension being regulated at will by the patient himself. Apparatus for fulfilling these indications is delineated in the accompanying sketches. Fig. 623

Fig. 623.

Fig. 624.

Kolbé's Apparatus for the Knee.   Modified Stromeyer's Splint for the Elbow.
represents Kolbé's contrivance for straightening the knee, and fig. 624 that of Stromeyer for rectifying ankylosis of the elbow.

Of the comparative harmlessness of these operations a good idea may be formed by the statistics furnished by Professor Nussbaum, of Munich. Of 110 cases of forcible extension of the knee, the condyles of the femur gave way in 32, and the tibia just below the attachment of the patella in 7, and yet no evil results ensued in a solitary one. I have myself broken up ankylosed joints in very numerous instances without any serious effects. Nevertheless, all such operations should be conducted with the utmost caution, especially when performed with the aid of machinery, as they may eventuate not only in fracture of the bones, either at the articulation or in its immediate vicinity, but give rise

to consequences still more disastrous, as violent inflammation, erysipelas, gangrene, and even loss of life.

Finally, when it is found that there is no possible chance of effecting a cure, but that ankylosis is inevitable, every effort, compatible with safety, should be made to place the affected limb in a situation most conducive to its future usefulness. Thus, the hand should be extended in a straight line with the forearm in ankylosis of the wrist; the forearm bent at a right angle with the arm in ankylosis of the elbow; and the arm brought close to the antero-lateral aspect of the body in ankylosis of the shoulder. In ankylosis of the hip, the thigh is slightly flexed upon the pelvis; when the knee is concerned, the leg is inclined somewhat backwards; and in ankylosis of the ankle, the foot is placed at a right angle to the leg; the parts being found to be most serviceable when held in these several positions. Particular occupations may, however, render it proper to deviate from these rules. Thus, Mr. Bryant, had under his charge a painter who desired that his arm might be ankylosed in the straight position; and a turner, whose leg, at his own request, was allowed to remain at a right angle with the thigh, as he was thus the better enabled to move his wheel.

Osseous ankylosis of the hip-joint was formerly considered as incurable, except by certain operations, one of which consists in dividing the bone, as originally proposed and successfully executed by Dr. John Rhea Barton, in 1826. His patient, a sailor, twenty-one years of age, had lost the use of his hip-joint, by an injury from a severe fall on shipboard. The thigh was drawn up nearly at a right angle with the pelvis, the knee projecting inwards across the sound limb, and the foot presenting forwards. All attempts at correcting the malposition having failed, a crucial incision was carried through the integument, over the most prominent part of the great trochanter, when, raising the flaps thus defined the muscles connected with this portion of the bone were detached, a passage being thus made both in front and behind the femur for the easy introduction of the finger. With a saw constructed for the purpose, the bone was divided through the great trochanter and a part of its neck in a transverse direction. The wound being lightly dressed, the limb was placed in a fracture apparatus, and the case managed upon strictly antiphlogistic principles. Passive motion was instituted at the end of three weeks, and repeated, from time to time, for four months, when the artificial joint had acquired such a degree of motion that the man was able to walk merely with the aid of a cane. The wound had healed, and he could not only rotate and abduct the foot, but carry it forwards and backwards over an area of upwards of twenty inches. Gradually, however, the use of the new joint was completely lost.

Dr. J. Kearney Rodgers, of New York, in 1830, modified the procedure of Barton, by excising a disk of bone from between the trochanters of a man forty-seven years old. The operation was successful, and the motions of the new joint persisted for two years and a half.

Professor Sayre, in 1862, removed a plano-convex piece of bone from between the trochanters, as shown in fig. 625, from Erichsen, and then rounded off the upper end of the lower fragment, so as to imitate the form of a superficial enarthrodial articulation. One of the great merits of the procedure is the point of transverse section, through which the attachment of the psoas and iliac muscles is preserved for the purpose of flexion. In his first case some necrosis occurred, but six years subsequently the patient enjoyed a good use of the limb. In a second case there was limited necrosis up to the date of the death of the patient from lung complications, six months after the operation, when the parts were found to be furnished with a capsular ligament, articular cartilages, and a synovial membrane.

Fig. 625.

Lines of Section in Sayre's Operation for Ankylosis of Hip-joint.

Of 17 cases of Barton's, Rodger's, and Sayre's open operations, 7 died, and in one performed by Professor Post, and which was an example of the first method, the femoral artery and vein were found on death from gangrene to be hooked over the divided end of the bone. This large mortality, when considered in connection with the extreme rarity with which a movable false joint has resulted, is quite sufficient to condemn these procedures for the simpler and more successful subcutaneous osteotomies.

Professor Volkmann, in 1873, modified the procedure of Rodgers, by making an incision along the posterior face of the great trochanter, separating the periosteum for two-thirds of its circumference, and removing with chisels and gouges

a triangular piece from just below the trochanter, and then forcibly breaking the inner circumference of the bone, after which he brought the limb parallel to the longitudinal axis of the body, and retained it in this position until consolidation had taken place. Of twelve operations conducted by Volkmann in this way, under antiseptic precautions, all recovered.

Mr. William Adams, of London, in 1870, reported the case of a man, twenty-four years of age, upon whom he had some months previously successfully performed subcutaneous division of the neck of the thigh-bone within the capsular ligament, on account of ankylosis of the hip-joint attended with extreme deformity. The instruments employed were a long tenotomy-knife, and a narrow saw with a cutting edge an inch and a half in length, fig. 626. After the section of the bone in the direction shown in fig. 627, it was necessary to divide the tendons of several of the femoral muscles in order to straighten the limb. The wound was slow in healing; but no severe inflammation or deep suppuration followed the operation, and bony ankylosis, with the limb in a straight position, was obtained. Of 34 cases in which this operation has been performed, only 3 proved fatal, one from pyemia, one from profuse suppuration, and one after consecutive amputation at

Fig. 626.

Fig. 627.

Adams's Saw for Subcutaneous Division of the Neck of the Femur.

Showing the Point where the Neck of the Femur is Divided in Adams's Operation.

the hip-joint. The procedure is particularly adapted to those cases in which the head and neck of the bone preserve their normal size, as when the ankylosis is the result of rheumatism or injury. Instead of making a clean section of the bone with a saw, Billroth resorts to the chisel and forcible fracture.

When the neck of the femur is materially altered in form, or partially destroyed, changes which frequently occur in tubercular osteitis, the shaft of the bone should be divided subcutaneously with Adams's saw just below the lower trochanter, as was originally practised by Gant, in 1872; or the section may be made with the chisel, as recommended by Maunder, the former instrument, however, being preferable. The procedure is comparatively safe, having been uniformly successful so far as I have have been able to learn. Under similar circumstances, Barwell prefers to make an oblique section, begining just above the small and terminating a little below the middle of the square face on the outer aspect of the great trochanter. Both of his patients recovered with useful limbs.

The most recent of the operations for the relief of bony ankylosis of the hip-joint, is that of Volkmann, which consists in forming a false-joint in the following manner: An incision having been made along the posterior surface of the great trochanter, the bone is divided one inch below the upper border of that epiphysis, the interior of the neck of the femur is fractured, and the head of the bone is removed by scooping out the interior of the acetabulum with a gouge. The upper end of the femur is next rounded off with a chisel and reduced in diameter to the size of the shaft of the bone, and then placed in the cotyloid cavity. The limb is subsequently extended by weights, and early passive motion resorted to. Volkmann has resected the joint in this way six times, and all the patients were enabled to walk and sit without elevating the pelvis.

The operation of Dr. Barton, above described, was modified by him, in 1835, in such a manner as to render it particularly applicable to the relief of deformity of the lower extremity, dependent upon *ankylosis of the knee-joint*. The case was one of complete bony ankylosis, in a medical man whose leg was flexed nearly at a right angle with the thigh, and who recovered with an excellent use of his limb.

The operation, as performed by Dr. Barton, consists of four distinct stages. In the first, a triangular flap is formed of the soft parts in front of the limb, consisting of the integument and the extensor muscles, by making two horizontal incisions, one just above the superior border of the patella, and the other two inches and a half higher up, down to the bone. This flap, which has a broad base on the inside of the thigh, is then dissected up, and held out of the way. The next step is to remove a V-shaped portion of

the femur, which is easily done with a narrow saw, care being taken not to divide the bone completely, for fear of injuring the popliteal artery, as happened in a case reported by Professor Ried, of Jena. In the third stage the bone is fractured by gently extending the limb; and, lastly, the flap is replaced and secured by suture. The dressing is completed by putting the limb upon a double inclined plane, where it is retained for the next ten days, or until the ends of the broken bone are enveloped in plastic matter, when it is placed nearly in the straight position, in a suitable apparatus for insuring quietude. The patient is usually able to rise, and walk about on crutches, in six weeks, or much sooner, if the immovable dressing is applied.

The sawing of the bone constitutes one of the leading objects of interest in this operation; if the wedge-shaped piece is too large, there is a possibility of non-union, whereas, if it is too small, it may be impracticable to straighten the limb sufficiently. In order to avoid these contingencies, all that is necessary is to measure the angle of deformity, and then to saw out a portion of bone equal to the complement of that angle. The adjoining cut, fig. 628, will afford a better idea of the nature of the operation than any description of it, however elaborate.

Dr. J. Kearney Rodgers modified this operation by connecting the ends of the bone with silver wire, on the supposition that the procedure would tend to expedite their reunion.

Fig. 628.

Barton's Operation.

Such a measure, however, is hardly required if proper care be taken to keep the limb well secured during the after-treatment.

Of 16 cases of this operation, of which the results have transpired, 14 recovered and 2 perished, respectively of hectic irritation and exhaustion. The success would thus seem to be eminently flattering.

In 1844, Dr. Gurdon Buck, of New York, in a case of complete synostosis of the knee with the limb at a right angle, so modified and extended the procedure of Barton as to remove the condyles of the femur, the head of the tibia, and the patella, in a wedge-shaped piece, thereby bringing the leg almost in a straight position. The patient, a man twenty-two years of age, suffered considerably from subsequent inflammation and suppuration; but at the end of six months the bony union at the knee was firm, and the limb shortened five inches. This operation has been practised in 39 cases, of which 5 proved fatal. The best result obtained from it, was in a case reported by Dr. Heuser, in which firm, osseous union took place in ten weeks, the man being afterwards able to pursue his vocation of a chamois hunter.

An operation for the relief of bony ankylosis of the knee, based upon the same principles as that of Dr. Barton, but differing from it in some essential particulars, was performed by the late Professor Pancoast at the Clinic of the Jefferson Medical College in the winter of 1859, the patient being a youth on whom extension had previously been tried in vain. It consisted in perforating with a stout gimlet the femur subcutaneously, through a single opening, at half a dozen points, just above the knee, and then forcibly breaking the bone. The limb was placed in appropriate apparatus, the upper end of the inferior fragment forming an angle with the apex projecting into the ham. A large abscess formed at the seat of fracture, but, with this exception, the case progressed favorably, and the boy made a good recovery, the foot coming down well, and the limb being nearly as straight as could be desired in such a condition of the knee-joint. In a case in the hands of Professor Agnew extensive suppuration also ensued, but the lad, after much suffering, finally got well.

An operation similar to the above was performed by Professor Brainard, in 1860, upon a man twenty-three years of age; but in this case the femur was divided through its condyles by means of a perforator. The patient recovered with a good limb. In a second case, one of false ankylosis of the knee, the patella was detached subcutaneously from the femur and tibia, and excellent motion of the joint obtained.

The operation of perforating the femur subcutaneously, and then forcibly fracturing the bone, has been performed only, so far as I know, in six instances, all of which recovered with useful limbs.

In 1861 I extended these subcutaneous operations to perforation of the joint itself, with disruption of the osseous adhesions between the bones entering into its composition. The instrument with which the operation is conducted, exhibited in fig. 629, consists of
a shaft of well-tempered steel, four inches and a half in length, the point of which is one-sixth of an inch in breadth, and presents on each side an oblique groove with cutting edges, so that it acts as a gouge as well as a drill. This is fitted into a firm handle, its proximal extremity being large, smooth, and rounded, so as to rest comfortably in the palm of the hand. In some instances, as when the bony connections are so firm as to resist the action of the drill, a narrow, sharp-pointed chisel, or Adams's saw may be used as a substitute. Whatever may be the form of the instrument, great caution must be exercised in operating on the posterior surface of the joint, lest it slip and injure the popliteal vessels.

The following case, transcribed from my clinical records, exemplifies the mode of performing the operation, the trifling suffering which generally follows it, and the after-treatment. A man, twenty-two years of age, was admitted into the hospital of the Jefferson Medical College, on the 30th of October, 1861, on account of bony ankylosis of the left knee, the leg being flexed at nearly a right angle with the thigh. Nine years previously, while engaged in mowing, he accidentally opened the joint with a scythe, the injury being followed by violent inflammation and constitutional disturbance. During his prolonged confinement, the limb was placed in a very bent position, in which it became stiffened, compelling him to use a crutch. A scar marked the site of the original wound, and the integument about the joint was indurated, and the seat of the cicatrices of old sinuses.

Fig. 629.

Bone-Perforator.

The diagnosis was synostosis of the knee, and was based on the absolute immobility succeeding traumatic inflammation, a fixed state of the patella, a sensation to the touch of thorough consolidation of the articulation, the absence of tension and resistance of the flexor muscles on attempts at forcible extension, and freedom from pain both in front and behind the joint during similar efforts.

Chloroform having been administered, a longitudinal incision, hardly half an inch in length, was made over the outer surface of the knee, near its middle, in a line with the groove between the head of the tibia and the external condyle of the femur, down to the two bones. Through this opening the drill was introduced, and passed on to the opposite side, when it was moved about in such a manner as to cut through and break down the osseous connections between the femur and the tibia on the one hand, and the femur and the patella on the other. The union was exceedingly firm; but after much difficulty, it was finally overcome, and by forcible extension of the limb, the parts yielded with a crackling noise. The small wound was carefully closed with two twisted sutures and collodion, and a roller carried from the toes to within a short distance of the groin. The leg was brought to an angle of about 45° with the thigh, and laid in an easy position upon its outer surface, a thick pillow being placed behind the knee. No blood was lost in the operation, and no pain experienced. Half a grain of sulphate of morphia was administered as soon as the effects of the anæsthetic had passed off, and recumbency, light diet, and cooling drinks enjoined.

No constitutional disturbance followed the procedure, the entire immunity from suffering being, doubtless, due to the fact that the natural structures of the joint had been completely destroyed. For four days the limb was allowed to remain perfectly quiet, when an extending apparatus was applied, and the leg was straightened daily several degrees. On the tenth day when the dressings were removed, the wound was found to be perfectly united, and at the expiration of three weeks the patient was permitted to go about on crutches. In the sixth week he was discharged well. At this time bony union was firm, the knee being slightly flexed, and the leg shortened one inch.

Fig. 630.
Result of Operation for Synostosis of the Knee.

The adjoining sketch, fig. 630, from a photograph, exhibits the appearance of the limb, two years after the operation. The muscles were as plump and as well developed as in the sound member.

This operation has been done successfully in seven instances, five having occurred in my own practice. In two of the latter preliminary division of the hamstring tendons was demanded, and in all firm bony union was procured with about one inch of shortening, which was deemed advisable to render locomotion less awkward. The treatment was not any longer than that required for simple fracture of the femur, the mean duration of confinement in bed having been twenty-three days, and the average length of time, in which the patient was unable to walk without artificial aid, ten weeks. In only one instance was the resulting traumatic fever alarming, and its occurrence could only be referred to the fact that the synostosis was not complete. The operation, indeed, should only be performed when the ankylosis is osseous throughout, as this renders the joint perfectly tolerant of rough interference. In such cases the synovial membrane and cartilages are destroyed, and the bones forming the articulation are firmly soldered together, as it were into one continuous piece, as in fig. 622, page 1092. Under ordinary circumstances, where the bond of union is soft, or the ankylosis false, and the least particle of motion is preserved, so rude a procedure would be attended with great risks, if not followed by fatal results, and could not be too strongly condemned.

2. *Extraärticular Ankylosis.*—In extraärticular ankylosis, the spurious ankylosis of some authors, the articular structures retain, at least for a time, their normal characters, but their functions are impaired or suspended by the diseased condition of the surrounding parts. Several distinct causes may induce such a result, of which muscular contraction, vicious cicatrices, osseous deposits, and the pressure of new growths, or aneurismal tumors, and paralysis of the articular muscles, are the most common and efficient.

a. Of the several causes here enumerated as capable of producing rigidity of a joint, permanent contraction of the muscles and tendons, which naturally influence and control its movements, is the most frequent. Examples of this are constantly met with in gout, rheumatism, fractures, and dislocations, where, from an extension of the inflammation which attends these diseases and accidents, motion is greatly impeded, if not completely destroyed, by this occurrence. The influence exerted by permanent contraction of the muscles is well illustrated in clubfoot and analogous distortions, where the joints are not only crippled in their functions, but greatly changed in their form and relations, giving the limb that peculiar aspect, from the resemblance to which it derives its name. Similar effects may be caused by the contraction of the aponeuroses.

β. Secondly, a joint may become stiff from a vicious cicatrice, as that, for instance, of a burn or scald. The tendency of the new substance is to continue to contract until in many cases it produces the most hideous deformity, stretching the soft parts to their utmost capacity, and drawing the neighboring articular surfaces completely out of their natural position. The morbid adhesions formed after ulcerative ptyalism generally give rise to distressing and often irremediable ankylosis of the temporo-maxillary articulation.

γ. In gout, rheumatism, and other affections, as well as in certain accidents, the motions of the joints are occasionally destroyed by the formation of osseous bridges, extending across the articulation from one bone to the other. Such an occurrence is most frequently met with in the sacro-iliac symphyses, and in the joints of the vertebræ; it sometimes occurs also in the more perfect joints, especially the ginglymoid. In fractures, followed by exuberant callus, the muscles and tendons, in the vicinity of the neighboring joint, may be so completely imprisoned by the new matter as to cause ankylosis of the worst kind.

δ. Ankylosis may be produced, in greater or less degree, by the development of various kinds of tumors, or morbid growths, in the neighborhood of an articulation, or in direct contact with it, interfering with its functions, and ultimately, if not removed, perhaps annihilating them. Thus, an aneurism of the popliteal region may cause stiffness of the knee, and a sarcoma of the jaw, partial ankylosis of the the temporo-maxillary joint.

ε. Finally, paralysis of the muscles of a joint may induce a certain degree of ankylosis; cases are constantly observed where, from long disuse of an articulation from this cause, its functions are permanently lost. The shoulder-joint frequently becomes stiff and useless, from palsy of the deltoid interfering with its natural movements.

It is extremely probable that the most of the causes here enumerated may, if long continued, induce permanent ankylosis, in consequence of the operation of the general pathological law, that, when a part ceases to perform its functions, it gradually degenerates, and is ultimately completely deprived of its characteristic attributes. Nature abhors everything

that is useless, and, when a joint is once rendered passive, the synovial membrane, losing its secreting faculty, becomes dry, and is at length converted into fibrous tissue.

The *treatment* of extraärticular ankylosis must be regulated by our knowledge of the nature of the exciting cause, which should, therefore, always be clearly ascertained before any attempt be made to interpose any curative agents. Thus, if it be found to depend upon contraction of the muscles, tendons, or aponeuroses, whether singly or unitedly, the only remedy, in confirmed cases, is their subcutaneous division ; whereas, in recent cases, it may often be relieved by a course of friction, douching, and passive motion, aided by gentle exercise on the part of the patient. Vicious cicatrices must be cut out, and, if possible, replaced by new substance ; such a procedure, however, is not always practicable, and, therefore, most cases of this description proceed from bad to worse until they are rendered wholly irremediable. Osseous bridges, circles, or bands may occasionally be removed with the saw and pliers ; morbid growths are exsected, or, as in aneurism, the artery leading to it is tied ; and paralysis of the muscles is relieved by stimulating frictions, the cold douche, shampooing, and electricity, the general health being at the same time improved by tonics, alterants, and exercise in the open air.

SECT. X.—NEURALGIC AND HYSTERICAL AFFECTIONS.

The joints are occasionally the seat of neuralgia, although not nearly so often as is generally imagined, especially if it be regarded as an independent lesion. As a complication of coxalgia and other articular affections it is sufficiently frequent. It is not improbable that in many of the cases in which it is referred to the joints, it is in reality situated altogether exterior to them, in the structures immediately around, and not in those directly concerned in their composition. Its most common sites by far are the knee and hip. As an independent affection, neuralgia is most frequent in young, delicate, nervous females, soon after the appearance of the menses, of the derangement of which it is occasionally an exponent. No period of life, temperament, habit, or occupation, however, is exempt from it. The attacks are sometimes strictly periodical, precisely like those of an intermittent fever, coming and going regularly once a day, or every forty-eight hours ; but more frequently they are irregular, the patient being tormented nearly incessantly, the pain being now slight, now severe, and then, perhaps, again entirely absent, although never very long at one time. The paroxysms are often coincident with neuralgia in other parts of the body, alternating with it, usurping its place, or going on with it simultaneously. The pain is either of a dull, heavy, aching character, or sharp, lancinating, and darting, flying about in fits and starts, in different directions, almost with the rapidity of lightning. It is usually attended with more or less soreness and tenderness on pressure, motion, and percussion, and sometimes with a slight degree of tumefaction or puffiness of the parts around the affected joint, which often entirely disappears in the intervals of the attacks. Motion also is usually somewhat impeded, and, when the hip is involved, there may even be considerable deformity of the lower part of the spine and of the pelvis. In the more aggravated cases the whole limb may be swollen, tender, and disabled ; and then there is commonly also a sense of numbness, extending to the very extremity of the member. The general health is not always appreciably affected ; often, however, there is marked disorder of the digestive organs, with a sallow state of the skin, headache, constipation, and derangement of the renal secretion. In the female the symptoms are often of an hysterical character, and are liable to frequent exacerbations in consequence of the peculiar state of the mind, which is generally morbidly sensitive, and absorbed in selfishness and disagreeable forebodings.

It is of great moment to discriminate carefully between neuralgic and other affections of the joints, inasmuch as a wrong diagnosis may lead to serious errors in practice, inducing, perhaps, the employment of harsh measures when gentle alone are required ; or, on the other hand, allowing the patient to move about and exercise the joint when he ought to observe the most perfect quietude. In general, the history of the case, the peculiar nature of the pain, the suddenness of the attack, the absence of constitutional disturbance, and the perfect freedom of motion of the affected joint, when the surgeon takes hold of the limb and attempts to carry it about in different directions, especially when the patient is under the influence of anæsthesia, will serve to distinguish it from organic disease of the articulations. When, however, there is any doubt respecting the real nature of the complaint, the examination should be repeated again and again, and

varied in every possible manner, so as to elicit the true state of the case. In many instances the best diagnostic is the success or failure of antineuralgic remedies.

In the *treatment* of articular neuralgia the first object should be to ascertain, if possible, the nature of the exciting cause, and then to direct our remedies accordingly. Attention to the diet, bowels, and secretions should, throughout, be kept prominently in view. The malady very often has its origin in a vitiated state of the alimentary canal, or in the suppression of some important habitual discharge, by correcting or restoring which the symptoms frequently disappear without any further effort. In general, however, antineuralgic remedies, properly so called, will be needed, and of these the best, unquestionably, are quinine, strychnia, and arsenious acid, in doses varying from three to five grains of the first, with the sixteenth of a grain of the second, and the tenth of a grain of the last, three times daily. When there is marked evidence of anemia, iron may be advantageously combined with these articles. If, on the other hand, the patient is plethoric, from the sixth to the eighth of a grain of tartar emetic may be added to each dose, with a view to its relaxing and diaphoretic effects. Morphia also forms a valuable adjuvant, and can rarely be dispensed with. Colchicum often proves very serviceable, affording prompt relief when everything else fails. It is particularly valuable when the disease partakes of a rheumatic or gouty character.

As topical remedies the most reliable are, soap liniment, with a liberal addition of laudanum and chloroform, kept constantly upon the part with a piece of flannel; the steam of hot water, conveyed to the joint from a tube connected with a boiler near the bed; frictions with atropia, veratria, or aconite ointment; and the employment of electricity. Leeches may be used when the articulation shows evidence of being inflamed, although they will generally be found to afford only very transient relief. Motion of the affected limb, especially in protracted cases, is usually highly beneficial, and should not be neglected.

The *hysterical* form of this affection appears to be much more common in England than in America, where, judging from personal observation, it is quite infrequent both in town and country. Sir B. C. Brodie, who was the first to call attention to it, declares that, among the higher classes of society in London, at least four-fifths of the female patients, supposed to labor under disease of the articulations, labor merely under hysteria. The pain, generally excessively severe, is aggravated by the slightest motion and pressure, and is usually confined to one particular spot, from which, however, it is liable to shift to other points. It is frequently associated with exquisite morbid sensibility of the surface, and is commonly located, not in the joints, but in the parts around them; often, indeed, apparently in the skin, or in the skin and muscles. Spinal irritation often exists, the extremities are cold, the pulse is small and feeble, the countenance is pale, the breathing is, at times, much embarrassed, the bowels are irregular, and the stomach is oppressed with flatulence. The disease is most common in young girls soon after the age of puberty.

Intense pain is sometimes experienced in the joints, especially in the ilio-femoral, as a result of endometritis. A probe introduced into the womb causes excessive suffering, darting with the rapidity of lightning into the hip, groin, and pelvic region. Occasionally a certain amount of tumefaction exists, but, generally, the parts have a perfectly normal appearance, and hence the true nature of the case is seldom fully comprehended by the professional attendant.

In the treatment of this disease assafetida and valerian often prove highly efficacious, especially if combined with chalybeate tonics. When the disease is associated with disorder of the menstrual function, great advantage will generally accrue from an occasional aloetic purge and the steady use of the compound iron mixture. Bromide of potassium, in large doses, is an excellent remedy, particularly serviceable in cases attended with loss of sleep and general nervous disorder. Chloral, too, often affords great and immediate relief. In many cases these two articles may be advantageously exhibited together. Monobromide of camphor, in doses of three to five grains, twice a day, occasionally affords marked benefit, and is sometimes highly efficacious. The cold bath, change of air, residence at the sea shore, and exercise on horseback, are often serviceable in effecting relief. Brodie relates a number of cases in which the disease was almost cured by an accident, as a fall or blow upon the affected articulation. The suffering of the joints, dependent upon endometritis, always promptly disappears upon the removal of the exciting cause.

SECT. XI.—DISLOCATIONS.

1. GENERAL CONSIDERATIONS.

A dislocation, or luxation, is the sudden and forcible removal of one articular surface from another, either as an effect of external violence, of inordinate muscular contraction, or of a diseased condition of the component structures of the affected joint.

As all joints are necessarily composed of two or more bones, the question naturally arises, which should be considered as the luxated one? Upon this subject all surgical authorities are, I believe, agreed. In every accident of this description the bone nearest the trunk is regarded as the fixed bone, and the one articulated with it as the dislocated. Thus, in luxation of the shoulder-joint, the scapula retains its normal position, either actually or suppositiously, while the humerus is thrown off the glenoid cavity, at one time in this direction, and at another in that. In dislocation of the elbow, the ulna and radius are forced away from the humerus, the latter serving as the fixed point. The same rule obtains in regard to all the articulations of the inferior extremity.

Dislocations are divisible into simple and complicated, complete and incomplete, primitive and consecutive, recent and old, single and double. When the accident occurs before birth it is designated by the term congenital.

A luxation is said to be simple when it is unaccompanied by anything more than a slight rupture of the ligaments, or of the ligaments and muscles. Although such an accident is usually produced by external force, as a blow or fall, it may occasionally arise purely from muscular action, especially when it is favored by disease of the affected joint.

In a complicated dislocation there is, in addition to the loss of relation between the two contiguous surfaces, some serious lesion of the soft parts, as, for example, a wound communicating with the displaced bone or opening directly into the articulation, laceration of important vessels or nerves, contusion of the skin and muscles, or fracture of the luxated bone. When the wound penetrates the affected joint, the accident is usually called a compound dislocation.

A complete luxation is one in which the head of a bone, totally removed from its corresponding articular surface, effects a lodgment in a new situation, as, for instance, when the head of the humerus is forced down into the axilla, resting against the border of the scapula, below the glenoid cavity. In an incomplete luxation, on the contrary, the articular surfaces, although they have lost their relative position, remain still partially in contact with each other.

In primitive dislocation, the displaced bone remains in the position into which it was originally forced; in consecutive, it abandons its first situation, and is fixed in another. Such an accident, however, can only happen, as a rule, when the luxation depends upon some organic disease of the articular surfaces, allowing them gradually to separate from each other, either by the mere weight of the corresponding limb, or by the action of the neighboring and associated muscles. In the traumatic form of the injury such an event must be exceedingly rare, although we must admit its possibility, the dislocating agent forcing the bone at once to the greatest verge of its displacement; or, as not unfrequently occurs, its further progress is effectually arrested by some opposing osseous prominence or some tensely strung soft part, as a tendon, muscle, or fibrous membrane. Luxation of the knee-joint from caries of the articular surfaces furnishes a characteristic exemplification of these two kinds of displacement. In this accident the head of the tibia gradually forsakes the condyles of the femur, slipping back into the popliteal region, whence, in time, it is drawn up against the posterior surface of the bone by the flexor muscles, thus suffering secondary luxation. A similar occurrence, although exceedingly uncommon, may, nevertheless, happen in a very robust subject in traumatic dislocation of the hip, shoulder, or lower jaw, where the force is barely sufficient to lift the head of the bone out of its socket upon, but not over, its rim, from which it is afterwards removed either by mere muscular contraction, or by the conjoint influence of this and the weight of the part connected with the displaced bone.

The terms recent and old refer merely to the duration of the injury, and might seem, at first view, to require no particular explanation. The propriety of this, however, will be rendered at once obvious if the question be asked, when does a dislocation become old? does it become old in a few days, or weeks, or months? So far as mere time is concerned, no lesion of this kind can be regarded as old unless it has existed for at least from six to twelve months; but if we look at the subject in reference to the ability of the

surgeon to restore the affected joint to its natural relations, it will be found that, while one dislocation may not be old at the end of several months, another may become so within the first few weeks. Thus, a luxated shoulder may frequently be successfully reduced after a lapse of two months, or even considerably later, whereas if an attempt be made to restore a dislocated elbow at the end of one-third or even one-fourth of that time, signal failure will generally follow. The import of these two terms, then, is one of much greater importance than has commonly been admitted, having, practically considered, a positive value and significance.

A single dislocation is one in which only one joint is involved; in the double form of the accident, on the contrary, the corresponding joint is likewise affected. The lower jaw suffers more frequently in the latter way than any other bone, but a similar displacement is also occasionally witnessed in the humerus, ulna, radius, clavicle, femur, and fibula. Double luxations may be complete or incomplete, simple or complicated.

Joints which admit of varied and extensive motion are much more prone to this injury than such as enjoy only a very limited motion. Hence, what are called the ball and socket joints, of which those of the hip and shoulder are the best representatives, suffer much oftener than the ginglymoid, as those of the elbow and knee. The tables of Malgaigne prove that dislocations of the shoulder are more frequent than those of all the other movable articulations together, 321 cases out of 481 having occurred here. Comparing the relative proportion of cases in the two extremities, the same distinguished observer finds that they are seven times more numerous in the superior than in the inferior. These differences in the relative frequency of the lesion in different joints are, as already stated, clearly referable to the differences in their structure and functions. Of all the large articulations, that of the shoulder is the most insecurely constructed; the glenoid cavity is remarkably shallow; the capsular ligament is long and loose, and the joint, admitting of every variety of motion, is under the direct influence of numerous powerful muscles, and exposed to numerous accidents. Why, then, should it be surprising that it is so often the seat of dislocation? The hip-joint, on the contrary, is the most admirably contrived joint of which it is possible to form any conception; as a piece of mechanism it is perfect; the acetabulum is an immense socket, in which the whole head of the femur is literally buried, and to which it is still further secured by two powerful ligaments, the round and the capsular; and, in addition to all this, it is surrounded by numerous large muscles, which serve to support and protect it from injury. Thus constituted, this articulation is comparatively seldom the seat of dislocation, hardly, as compared with that of the shoulder-joint, in the proportion of 1 to 9½. The clavicle, which enjoys only a very limited degree of motion, is not unfrequently luxated, its exposed situation and its buttress-like office rendering it peculiarly prone to the accident, occupying, in this respect, nearly the same rank, according to Malgaigne's statistics, as the hip-joint.

Thus, recapitulating what is said above, it may be concluded that the most powerful predisposing causes of dislocation are, varied and extensive motion of the joints, want of firmness between the articulating surfaces, arising either from their shallowness or the structure and arrangement of their ligaments, and the exposed situation and peculiar functions of the bones entering into their composition.

The direction in which dislocations occur is subject to much diversity, depending upon the nature of the joint, and the direction in which the force is applied at the time of the accident. In the ginglymoid articulations the bones may be displaced backwards, forwards, or to either side; in the orbicular, as, for example, that of the shoulder, downwards, forwards, upwards, or backwards.

Although dislocations occur at all periods of life, they are by far most common in middle-aged and elderly persons. Of 643 cases, analyzed by Malgaigne, only one was noticed before the fifth year, and none after the ninetieth. The greatest number took place between the thirtieth and fifty-sixth years. The reason of these differences is to be found in the circumstance that the bones of the young subjects, being comparatively soft and pliant, and not yet everywhere completely solidified, yield most easily at their epiphyses and even at their shafts, while those of very old and decrepit persons are generally so brittle that it requires much less force to break than to luxate them. It is seldom that an opportunity is afforded of seeing a dislocation of the hip-joint after the age of sixty, while it is very common to meet with fracture of the neck of the femur within the capsular ligament. This statement, however, must be received with some degree of restriction, for it is obviously not applicable to all the articulations. The shoulder-joint, for instance, forms a striking exception, its dislocation in old age being much more frequent than fracture of the superior extremity of the humerus.

Causes.—The efficient causes of dislocation are external injury and muscular contraction. Most cases are due to the former, acting either directly upon the joint, or indirectly through some bone articulated with it. Dislocation of the shoulder, consequent upon a blow or fall upon its summit, affords a good illustration of the manner in which injury acts when applied directly to an articulation. In this case the force is spent upon the superior extremity of the humerus, propelling the head of the bone down into the axilla, beyond the glenoid cavity of the scapula. The femur may be luxated in a similar manner, by a heavy body falling on the hip, while the thigh is in a state of abduction. Lateral dislocation of the patella is another instance of displacement occasioned by direct violence. Sometimes a severe wrench is necessary to produce the accident, especially when the bones are connected by short and strong ligaments, requiring great force to separate them.

A more common mode of causing this accident is by the indirect application of force. Indeed, nearly all the dislocations of the upper extremity, and many also of the lower, are the result of violence, transmitted from the distal portion of the limb, and concentrated upon some particular bone, which thus loses its connection with the opposing surface. It is in this manner that falls upon the hand so often luxate the elbow, and even the shoulder, according to the point upon which the violence is exploded. Dislocation of the clavicle is usually induced by falls upon the shoulder, in which this bone is acted upon by two forces coming in opposite directions, the one being caused by the weight of the body, and the other by the object struck.

Of the ability of the muscles to induce this accident, experience has furnished ample proof. I have myself witnessed a number of examples of it, mostly in the shoulder, during attacks of epilepsy. In one, the accident occurred simply by raising the hand above the level of the head. Yawning is a common cause of dislocation of the lower jaw. Several cases have been recorded of displacement of the thigh-bone by muscular contraction. In the ginglymoid joints such occurrences must, for obvious reasons, be much less frequent than in the orbicular.

Some persons possess the power of dislocating certain joints voluntarily, simply by muscular action. Several such individuals have come under my own observation, but it was invariably noticed that, however powerfully they exerted themselves, they could not produce anything like a complete displacement of the articular surfaces, and it is, therefore, presumable that most of the examples that have been reported of this occurrence have been of this description. Dr. Haynes, of Saranac, New York, has published the particulars of the case of a lad, seven years old, who is said to be able to luxate, and also to reduce, the joints of the knee, elbow, wrist, thumb, and fingers, with perfect ease, by muscular contraction.

Fig. 631.

Dislocation of the Knee from Disease.

In all cases of dislocation, whether the result of direct or indirect injury or of muscular contraction, the accident is materially favored by a partial separation of the articular surfaces. The lower jaw cannot suffer displacement so long as it is closed, but if the chin be struck while the body is depressed, and the condyle drawn forward upon the anterior convex part of the temporal fossa, the slightest blow will suffice to throw the bone down over the root of the zygomatic process. Dislocation of the humerus into the axilla is greatly promoted by abduction and elevation of the arm. The femur is generally luxated upwards and backwards against the dorsal surface of the ilium, by falls upon the hip, and

the occurrence is always greatly facilitated by the circumstance of the patient having a heavy load on the back. A twisted or contorted state of the limb is generally highly conducive to the accident.

Organic disease of a joint may become a cause of dislocation, as seen in fig. 631. from a patient of Professor T. G. Richardson. The man had labored for a long time under an arthritic affection of the knee, which was gradually followed by permanent displacement of the head of the tibia backwards behind the condyles of the femur. There was no external disease of any kind. The head of the bone could easily be reduced, but not kept in position, owing, apparently, to the complete destruction of the ligaments of the joint.

2. SIMPLE DISLOCATIONS.

Dislocations are characterized by a certain train of symptoms, by which they may generally be easily distinguished from other accidents. Of these symptoms, the most constant and prominent are, loss of function of the affected articulation, lodgment of the displaced bone in an unnatural situation, deformity of the joint, and change in the mobility, length, and axis of the corresponding limb. To these may be added, as subordinate phenomena, the noise which is occasionally heard by the patient at the moment of the accident, numbness of the parts from pressure of the luxated bone upon the nerves, contusion and discoloration of the integument, together with pain, swelling, and crepitation as effects of the resulting inflammation.

Immediate and, generally, entire loss of function of the affected joint is a necessary consequence of a dislocation, however induced. Thus, in luxation of the temporo-maxillary articulation, the lower jaw is widely separated from the upper, and cannot be closed by any effort that the patient may make. When the principal joints of the upper extremity are affected, the person is unable, without assistance, to carry his hand to the head, or to execute the motions of flexion, extension, circumduction, pronation, and supination ; the whole limb feels heavy and numb, and requires to be supported by the sound one. In dislocation of the foot, leg, and thigh, progression is not only impracticable, but every attempt of the kind is attended with so much distress as to cause its immediate discontinuance. The loss of function necessarily persists so long as the joint remains unreduced, although, eventually, it is generally completely regained.

Impairment of the motion of the corresponding limb is an important symptom. The patient, in general, not only loses all voluntary control over the member, but the surgeon, upon taking hold of it, and attempting to carry it about in different directions, finds it impossible to effect his object. Motion, it is true, is not always completely abolished, but there is no case in which it is not considerably, if, indeed, not greatly, restricted. In some of the articulations, as, for example, in that of the elbow, the displaced bones are occasionally so thoroughly interlocked as to render it difficult, even by the most adroit and persevering efforts at extension and counterextension, to disengage them from each other, and restore them to their natural situation. Immobility, therefore, is one of the most valuable symptoms of dislocation. Its causes are threefold, muscular contraction, opposing osseous prominences, and constricting ligamentous bands, or all these united. A knowledge of these obstacles is of great practical moment, as it involves important therapeutic considerations, which cannot be too well understood.

In most cases the surgeon is able to feel the displaced bone in its new situation, beyond the limits of the corresponding articular surface. Sometimes, indeed, it may even be readily detected with the eye, by the prominence which it forms by raising up the muscles and integument. In order to ascertain the precise position of the bone, a careful examination will generally be required, especially when there is much tumefaction obscuring the symptoms. For this purpose one hand is placed upon the injured joint, while the other is employed in moving the corresponding limb ; when greater accuracy is necessary, this office is confided to an assistant, in order that both hands may be used for conducting the investigation. If the manipulation be productive of severe pain, it should be suspended until the system has been brought fully under the influence of anæsthesia. The distance to which the head of the displaced bone is thrown varies, in different cases, from a few lines to several inches, depending upon the size and shape of the joint, and the amount of force employed in producing the accident ; as a general rule, it is greater in the orbicular than in the ginglymoid articulations.

Deformity of the joint is commonly one of the most reliable symptoms. It usually manifests itself in a marked flattening of the articulation, as in dislocation of the humerus into the axilla, in which there is always a loss of rotundity of the cushion of the shoulder

from the manner in which the deltoid muscle is spread out ; or, in great increase of the width of the joint, as in lateral luxation of the elbow and knee. Sometimes the joint has a singularly contorted, angular, or twisted appearance.

A marked change in the length of the limb articulated with the displaced bone is generally present. It is seldom that the limb retains entirely its normal length ; most commonly this is either increased or diminished, the extent varying according to the structure of the joint and the degree of force employed to produce the accident. Shortening is the rule ; elongation the exception. Thus, in the various luxations of the shoulder and hip there is only one in each in which the limb is increased in length, while in all the rest it is considerably, if not greatly, shortened, amounting in some of them to several inches. No material difference exists in regard to this symptom in the dislocations of the orbicular and the ginglymoid articulations.

Dislocation changes not only the length of the affected limb, but also, in most cases, its axis, giving it a peculiarly contorted or twisted appearance. This deformity is nowhere more conspicuous than in the displacements of the elbow-joint, in some of which it is almost diagnostic. Another excellent illustration of this occurrence is afforded in luxation of the head of the humerus into the axilla, where this trait is often so well marked as at once to convince the practised eye of the nature of the accident. In most of the displacements of the orbicular joints the limb stands off at a considerable distance from the body, in a constrained and twisted state.

Of the subordinate symptoms there is not one that is of any actual value ; nevertheless, they are deserving of some consideration, if for no other reason than that of completing the history of this accident.

It is highly probable that most dislocations, at least those of the larger joints, are attended with some degree of noise at the moment of their occurrence ; but that this noise is not often heard by the patient may be assumed from the fact that he is so seldom conscious of it, owing to the confused state of mind into which he is thrown by the sudden and unexpected nature of the accident. Its character cannot be easily described, but it may, perhaps, be said to bear a closer resemblance to a crackling sound than any other to which it can be compared. It is, apparently, caused by the sudden and forcible separation of the articular surfaces, and is generally most distinct in luxations of the orbicular joints.

A considerable degree of numbness is occasionally felt in the parts immediately around the affected joint, and even in the whole of the corresponding limb. It evidently depends upon the compression of the nerves by the displaced bone, and is particularly distressing in the axillary dislocation of the shoulder, in which the tingling sensation often extends to the very tips of the fingers.

More or less contusion and discoloration are often present. The contusion may be accompanied by scratches of the skin, or even by considerable wounds, thus complicating the case. The discoloration varies from the slightest change of the normal hue to deep purple, depending upon the size and number of the injured vessels. Large quantities of blood are sometimes effused among the tissues in the immediate vicinity of the affected joint and even into the joint itself.

The pain consequent upon dislocations varies greatly in different individuals, often depending, perhaps, quite as much upon their idiosyncrasy as upon the severity of the injury. Its immediate cause, of course, is the rupture of the ligaments and other structures in and around the affected joint, and may, on the one hand, be so excessive as to induce fainting and other distressing effects, or, on the other, so insignificant as hardly to attract attention. It is always increased by manipulation and motion, as well as by the resulting inflammation, and may continue for days and weeks. In nervous, irritable subjects it occasionally assumes a neuralgic character. When the displaced bone compresses an important nerve, the pain is generally attended with a feeling of numbness and tingling.

More or less swelling always succeeds to dislocations ; sometimes almost instantly, but generally not under several hours ; at one time slight, at another exceedingly severe. When it appears suddenly, within a few minutes after the accident, it is always due to effusion of blood, and is then either attended or soon followed by discoloration of the integument. Coming on more slowly, it may reasonably be concluded to be the result purely of inflammatory deposits, especially of serum and lymph, or of these deposits and of blood combined. When the incited action runs very high, the swelling is generally proportionately great, the part being hard, stiff, glossy, painful, and intolerant of manipulation.

The friction-sound which occasionally attends recent unreduced dislocations has been ascribed to different causes; by some, as J. L. Petit, to dryness of the articular cartilages; by others, to the presence of a superabundance of synovial fluid; by Sir Astley Cooper, to a deposit of fibrin in the joint and the neighboring bursæ; by Malgaigne, to the rubbing of the head of the luxated bone against an osseous surface denuded of its periosteum. I am strongly inclined to the belief of the English surgeon that it is mainly, if not wholly, due to plastic effusion into and around the articulation, an idea strengthened by the fact that it can never be elicited until after the occurrence of inflammation. If it were occasioned by dryness of the articular cartilages, or denudation of the bone, it ought, as a natural consequence, to be perceptible immediately after the infliction of the injury.

The term friction perhaps expresses the nature of this sound better than any other that can be employed; it is entirely different from the grating noise and sensation caused by rubbing together the two ends of a broken bone; it is more like the sound occasioned by rubbing over each other two pieces of sole-leather; it is a soft, creaking, or crackling noise, not a grating one.

Diagnosis.—The accident with which dislocation is most liable to be confounded is undoubtedly fracture, especially fracture in the vicinity of the articulations, an occurrence not only quite frequent, but generally exceedingly embarrassing, on account of the difficulty of its diagnosis. The most constant and reliable symptoms of dislocation, as already stated, are, deformity, both of the affected joint and limb, loss of function, impaired motion, and difficulty of restoring the displaced bone to its natural situation. In fracture the most important characters are, distortion, preternatural mobility, and crepitation, with facility of reduction.

If these symptoms be compared with each other, it will be found that, although there is some resemblance between some of them, yet that, in the main, they are strikingly dissimilar, and, therefore, in so far, diagnostic of the accidents which they respectively serve to characterize. Deformity is common to both dislocation and fracture, and, for this reason, is of little, if any, value as a point of distinction between them. The same is true of the loss of function, which is often, perhaps generally, quite as great in the one as in the other. If a man with a luxated hip may occasionally support the weight of his body upon the affected limb, or even walk slightly upon it, he can sometimes do as much, and even more, when he has an impacted fracture of the femur, or a fracture of the neck of that bone temporarily unattended by a separation of the fragments. A dislocated jaw is quite as helpless as a broken one; in neither case can it perform the office of mastication. Both these symptoms, then, are without the slightest diagnostic value. But it is very different with the others above enumerated. Mobility, for example, is a differential sign of great significance. In dislocation, mobility is either entirely lost, or very much impaired; the displaced bone is more or less firmly fixed in its new situation, and can only be restored to its natural position by more or less powerful efforts, often long and anxiously continued. In fracture, on the contrary, there is always an increase of motion, or, more properly speaking, there is preternatural mobility, the limb allowing itself to be bent, extended, and even rotated upon its axis. Moreover, by extension and counterextension the member may readily be restored to its natural length and shape, but the moment these efforts are discontinued there is a reproduction of all the previous symptoms. Such an event never happens in dislocation; a bone once reduced remains reduced, unless accident should again lift it out of its socket. Lastly, in luxation the replacement is usually attended with a peculiar noise or snap, caused by the forcible contact of the opposing surfaces; in fracture no such noise is ever distinguishable. Crepitation is another valuable diagnostic in these accidents. In dislocation the only sound ever perceived is a kind of friction-sound, and even this is never present until after the supervention of inflammation; in fracture, on the contrary, crepitation is one of the most important symptoms; indeed, it is characteristic of the lesion. It may be detected immediately after the accident, and during all stages of the after-treatment up to the time of incipient union. Deformity and preternatural mobility may both be absent, and yet if there be crepitation, or a rough grating noise and feel upon rubbing together the ends of the broken bone, there can be no doubt respecting the real nature of the case. It is a fracture and nothing else. So, on the other hand, if there be deformity and loss of motion, with absence of crepitation, the rational inference is that the case is one of luxation, or, at all events, not of fracture.

Another valuable sign, but one which has only a general application, is the difference in the position of the affected limbs in the two classes of injuries. In dislocation the limbs often stand off at a considerable distance from the body, in a constrained and un-

seemly attitude; in fracture, on the contrary, they always hang close by the side of the body. Most of the displacements of the hip and shoulder joints exhibit this peculiarity, and I consider it as of no little value as a means of discriminating between these lesions and fractures of the superior extremities of the femur and humerus.

Contusion, discoloration, pain and swelling being common to both dislocation and fracture, are worthless in a diagnostic point of view. Instead of being of advantage in this respect, they generally only serve to embarrass the attempts at discrimination. Numbness, however, possesses a certain value, especially in some of the luxations of the shoulder and hip, where it occasionally constitutes a prominent and distressing symptom, which is never the case in fracture, except under very rare circumstances, as when the ends of the broken bone pierce, bruise, or compress a large nerve.

Important aid may sometimes be derived from a knowledge of the position which the dislocated bone is most liable to occupy. Thus, in displacement of the shoulder, the head of the humerus is usually thrown into the axilla, or forwards against the chest, seldom upwards or backwards; the most common luxations of the femur are those upon the dorsal surface of the ilium and into the sciatic notch. In the ginglymoid joints, especially those of the knee and elbow, posterior displacement is most common.

After all, however, no matter what may be the character or prominence of the symptoms, a correct and reliable diagnosis can only be attained by a thorough examination of the condition of the parts concerned. Without the light which such an investigation is capable of furnishing, no surgeon, however skilful or experienced, can always be certain whether the accident is really a dislocation or a fracture, or whether these lesions do not coexist. In conducting the examination, the same general rules are applicable as in fracture. The sooner, of course, it is made, the less likely will it be to occasion severe suffering to the patient, or annoying embarrassment to the practitioner. When the parts have become tumid and infiltrated, the nature of the accident is usually very much obscured, and the manipulation only aggravates the already existing mischief. Besides, they will then be so painful as to render it impossible to touch them unless the patient is under the influence of an anaesthetic. It is unnecessary to say that when a joint is in this condition, it must be handled with the greatest care and gentleness; yet, at the same time, the exploration should be thorough, otherwise it cannot be satisfactory, and if one trial is not sufficient, another should be made soon after the first, means being used, meanwhile, to allay pain and inflammation, in order to render the parts more tolerant of manipulation.

A careful measurement of the affected limb, or, rather, of the portion of the limb, between the affected joint and the one next below, often throws valuable light upon the diagnosis. Thus, if, in injury of the shoulder-joint, the distance between the acromion process and the elbow is found to be considerably greater than on the sound side, it will be a legitimate inference that the case is one of dislocation into the axilla, and not of fracture of the head or neck of the humerus. In luxation of the elbow backwards, the forearm is always sensibly shortened in front, while behind it retains its normal length. The measurement must be taken with a piece of tape, which, in order to insure greater accuracy, should always be graduated, the ends being applied against two fixed points, and the same operation being performed upon the sound limb.

When, notwithstanding all these examinations and precautions, the case remains doubtful, it will be well to adopt the suggestion of Malgaigne of inserting a long, slender needle into the joint, and also, if necessary, into the parts immediately around, with a view of ascertaining their precise condition. If a hollow be found where there is naturally a projection, or a projection where there ought merely to be a cavity, it may reasonably be presumed that the case is one of dislocation, and the conjecture will be converted into certainty if there be an absence of crepitation and preternatural mobility. There can be no possible objection to such an exploration, if due attention be paid to the larger vessels and nerves, and if the instrument be sufficiently slender to make only a small puncture, and so well tempered as not to break. It is surprising, when we consider the facility and safety of this operation, and the undoubted light which it is capable of affording in obscure cases of this accident, that it has not attracted more attention, or been more frequently employed.

Finally, dislocations are sometimes painfully simulated by sprains, so much so, indeed, as to puzzle and perplex the most sagacious observer. In such an event, nothing short of the most patient and accurate examinations and measurements, repeated again and again, both in the recumbent and in the erect posture, will be likely to prevent mistake.

Morbid Anatomy.—On dissecting a joint that has been recently luxated, the head of the bone will be found to be more or less removed from its socket, the distance to which it has been thrown ranging from a few lines to several inches, according to the structure of the parts involved, and the degree of force concerned in producing the accident. In the incomplete form of the lesion the articular surfaces still partially retain their apposition, while in the complete all connection is lost. The displaced head rests either upon some muscle, tendon, or bone, or upon all these structures, and the socket is generally occupied with blood, either fluid, or partly fluid and partly coagulated. The ligaments are lacerated, elongated, and relaxed, the extent of the rent varying from a mere fissure, barely large enough to permit the escape of the bone, to almost complete separation from their osseous attachments. The capsular ligaments are usually more extensively torn than the band-like, and, in both cases, shreds of the injured structure are occasionally interposed between the bone and the parts upon which it rests. In dislocations from muscular contraction, as in those of the jaw and shoulder, slight laceration of the ligaments is generally conjoined with marked elongation, and dissection has rendered it probable that cases of this kind occasionally occur even without any rupture whatever. The muscles in the immediate vicinity of the injured articulation usually participate, at least to some extent, in the mischief sustained by the ligaments, being, like them, more or less stretched, contused, or even torn, although the latter occurrence is neither frequent nor extensive. The nervous trunks around the joint may be compressed and displaced by the luxated bone, but are rarely, if ever lacerated, or seriously hurt in any way. The same is true of the larger vessels, both arterial and venous, the hemorrhage which follows the accident, and which is usually quite insignificant, proceeding from the smaller ligamentous, connective, and muscular branches. If the patient has survived the accident several days, so that the parts have had time to become inflamed, more or less plastic matter will be found, both in the socket and in the neighboring tissues, matting and gluing them together.

Prognosis.—The prognosis of simple dislocations must be considered with reference to two circumstances, the restoration of the displaced bone, and the severity of the injury sustained by the accident. If attended to early, they may commonly be easily reduced, and are seldom dangerous either to life or limb. If, however, they are neglected, or improperly managed, more or less deformity and loss of motion must ensue, and the resulting inflammation may be so great as to cause serious constitutional disorder. Luxations of the orbicular joints are generally less hazardous than those of the ginglymoid, but they are nearly always more difficult of reduction, on account of the adjacent muscles being more numerous and powerful, and, consequently, more resisting. On the other hand, however, the displacements of the orbicular articulations retain their reducibility much longer than the ginglymoid ; thus, a luxated shoulder may often be restored at the end of several months, whereas a luxated elbow generally becomes irreducible within as many weeks. In children, old persons, and females, the restoration is generally more easily accomplished than in adults, or in strong, robust individuals, whose muscles are more developed, and, therefore, less easily subdued. This difference obtains, in the same relative degree, even when anæsthetics are used.

Treatment.—The leading indications in the treatment of simple luxations are, first, to restore the articular surfaces as soon as possible to their natural situation ; secondly, to keep the affected joint at rest until the lacerated ligaments and other structures have become repaired ; thirdly, to limit and subdue inflammation ; and, fourthly, to reëstablish the functions of the parts. The character of these indications, and the mode of fulfilling them, should be kept clearly and prominently before the eye of the practitioner ; for, unless he has accurate and definite conceptions upon the subject, he must often fail in accomplishing his object in a satisfactory and creditable manner.

In entering upon the consideration of the treatment of this class of accidents, the first question that arises is, what are the causes which oppose their reduction, or, in other words, why is it that dislocations do not disappear of their own accord? Until recently it was generally supposed that the principal barrier to the reduction was the resistance offered by the muscles connected with the displaced bone, contracting at first spasmodically, and then permanently, so as to hold the part firmly in its new position. To overcome this action of the muscles in the vicinity of the affected joint has, therefore, always been a leading indication in the attempts at reduction ; and yet how signally these attempts frequently fail, after the most thorough relaxation, not only of these muscles, but of the whole system, by anæsthetics and other means, as the lancet, tartar emetic, and the warm bath, is well known. This fact of itself, then, is sufficient to prove that, although muscular contraction is one of the main agents which oppose the reduction, it is not by any

means the only, nor always even the principal, one. If the difficulty depended merely upon the resistance of the muscles, whether spasmodically acting or temporarily shortened, the use of depressants and anaesthetics, aided by steady, persevering extension and counter-extension, ought to enable the surgeon to reduce, promptly and effectually, every dislocation whatever. But this is not the case; the patient, in former days, used to be bled to syncope, nauseated to the utmost with tartar emetic, and literally parboiled, and yet, half dead as he was, restoration was frequently impossible, and so it is still in these days of chloroform and ether. This, then, being the fact, other opponents, capable at least of aiding the muscles in their resistance, or of themselves sufficient to offer a serious, if not insuperable, barrier to the reduction, must be sought for. Such obstacles are found in the bones and ligaments, and but for these it would be difficult to conceive of any case of dislocation that could resist, more than a few minutes, any well-directed efforts at restoration. In truth, almost every dislocation would reduce itself. Why is it that the surgeon frequently experiences so much trouble in replacing a luxated thumb? Is it not because of the resistance offered by the prominences and ligaments of the affected joint? The muscles of the thumb can certainly not, as active agents, exert any serious influence in preventing the reduction; for cases have occurred where the luxated phalanx was literally torn away in unsuccessful attempts of this kind. In dislocation of the jaw, the principal obstacle to the reduction is the zygomatic process of the temporal bone; and, although the temporal, pterygoid, and other muscles usually contract with great power, yet this would rather tend to favor the reduction than to prevent it if the condyle of the bone were not firmly locked in the fossa below. The obstacle which bony prominences offer to replacement is well shown in the luxations of the shoulder and hip, the former being always comparatively easy of reduction, on account of the smooth and shallow state of the margin of the glenoid cavity, while the latter, in consequence of the opposite state of the rim of the acetabulum, are generally comparatively difficult. This resistance, however, is always, other things being equal, most striking in the ginglymoid articulations, owing to the greater complexity of their structure, and their larger size, but more especially to the greater number and bulk of the neighboring prominences and depressions, thus permitting the displaced bone to become more readily interlocked with the fixed one.

The most serious barrier to reduction is generally offered by the ligaments, caused by the small size or the peculiar shape of the rent made at the time of the accident, the bone passing readily through it, but being unable to return on account of the manner in which it is girt by the edges of the aperture; the membrane or cord being drawn over its neck like a purse with a tight string, or a button fastened in its hole. That this frequently happens in the capsular ligaments, in luxations of the orbicular joints, may readily be imagined when we take into consideration the difficulty of effecting reduction, however thoroughly the system may be relaxed, while, in regard to the funicular ligaments, or those of the ginglymoid articulations, the fact is abundantly attested by daily experience.

Finally, it is extremely probable that the reduction of certain dislocations is materially impeded, if not at times prevented by the head of the displaced bone becoming entangled among the neighboring muscles or tendons, producing an effect similar to that occasioned by the ligaments and bones.

The means which are usually employed for surmounting these several obstacles consist of certain manipulations or manoeuvres, as extension and counterextension, conjoined, if necessary, with pressure and thorough relaxation of the system.

Occasionally mere pressure, if properly directed, is sufficient to effect reduction, especially when the dislocation is seated in a joint with loose ligaments, or when the ligaments are extensively lacerated and the neighboring muscles are in a passive, crippled, or paralyzed condition. In general, however, more or less extension and counterextension will be required, and the mode of applying and conducting these becomes, therefore, a matter of paramount consequence. Upon these subjects much diversity of sentiment has existed among writers, some contending for one mode of practice, and others for another, as if it were possible to lay down any specific rules upon points of treatment which must necessarily vary according to the exigencies of each particular case. My own experience is that it is generally best to apply the extending power to the bone which is articulated with the luxated one, or, in other words, as far as possible from the site of injury. Many practitioners, however, select the distal portion of the displaced bone, under the supposition that it affords a more direct and influential leverage. In not a few instances, indeed, we are obliged to adopt this course from necessity, the nature of the case not admitting of any choice; as, for example, in dislocations of the wrist and elbow, and in the corresponding dislocations of the inferior extremity.

Extension and counterextension may be made by the hands of intelligent assistants, aided, if requisite, by lacs, napkins, sheets, or pulleys. As a general rule, the resisting power, or the counterextending means, should be fully equal to the extending, and both should be applied in such a manner as to create as little inconvenience and pain as possible; they should be exerted slowly and gradually, and at the same time continuously, the object being not to fret the muscles which oppose the reduction, but to fatigue and exhaust them. Indeed, any sudden and violent movements would only be followed by mischief. With regard to the extension, it should always be first made in the direction of the luxated bone, but in proportion as the resistance is overcome the limb should gradually be brought back to its natural position.

During the reduction the patient may sit or lie, as may be most convenient, or as the exigencies of the case may seem to demand. Whenever chloroform is administered, recumbency is indispensable. The patient, as a general rule, should lie upon a bed or table during the reduction of nearly all the dislocations of the principal articulations, especially those of the shoulder, hip, and knee; in those of the elbow, hand, ankle, clavicle, and jaw, on the contrary, the sitting posture will be found most convenient for the surgeon. The number of assistants must vary from one to three, four, or five, according to the nature of the case, and it will be of great benefit if their duties are always accurately defined before the operation is entered upon, otherwise delay, annoyance, and embarrassment will be sure to arise. The counterextending band, which generally consists of a folded sheet, a jack-towel, or, what is better, a long, stout piece of muslin, is fastened around the trunk or limb so as to diffuse its pressure over a considerable space, without the risk of injuring the soft parts, exciting the muscles in the neighborhood of the dislocation, or interfering mechanically with the return of the luxated bone. The extending band must also be secured with great care. The best plan is to envelop the surface of the limb to which it is to be applied with a soft, wet napkin, folded, and passed around at least twice. This answers the double purpose of protecting the skin and of preventing the noose or lac from slipping, which seldom fails to happen if a dry cloth be

used. The lac should be of sufficient strength not to break, and should be fastened around the napkin by means of the clove-hitch or sailor's knot, the proper method of making which will readily be understood by a reference to the accompanying sketches, figs. 632 and 633. Or, instead of this, we may use the French knot, which is equally efficient, and which is executed by placing the band across the limb so as to form a loop on each side, each end being then passed under the limb through the opposite loop. In

the more simple forms of dislocation, the requisite extension and counterextension may be made with the hands, or by the pressure of the heel, knee, or fist.

Pulleys, fig. 634, are rarely required for reducing dislocations, the use of anæsthetics and

Fig. 635.

Pulleys applied.

the " manual method," as it is termed, having well-nigh rendered their application unnecessary in all recent cases of the accident. I have myself not had occasion to employ them for many years, and there is reason to believe that, as we become better acquainted with the nature of the subject, they will ultimately be almost entirely dispensed with. There is no doubt that they have done immense mischief, even in the hands of otherwise judicious surgeons, and that they more frequently impede than favor reduction. A formal description of this instrument will be unnecessary here, as its appearance and office, known to every one, will easily be understood from the annexed representation, fig. 635. During its application the patient should be recumbent, one hook being fastened to a staple, fig. 636, in the floor or wall, and the other to the noose in the lac encircling the limb. The cord should then be tightened, either by the surgeon himself, or by a trustworthy assistant, the operation being performed with all possible care and gentleness, so as not to endanger fretting of the muscles, fracture of the bones, or rupture of any of the soft parts.

Fig. 636.

Staple.

To prevent the slipping of the pulley-rope, and at the same time distribute the pressure so as not to bruise the limb, recourse may be had to the ingenious contrivance, fig. 637, devised by Dr. Levis. " It consists," says Dr. Roberts, " of a strong iron hook, the upper part of which is attached to a flat plate about seven inches long and two wide. This plate is slightly curved transversely

Fig. 637.
Levis's Apparatus for fastening Pulley-rope to Limb.

to apply itself to the limb, and is roughened. On the upper surface of this plate, at each side, there extends a serrated longitudinal ridge in which the cord attaching the plate to the extremity is caught as it encircles the limb." The contrivance answers equally for the upper extremity.

A very ingenious contrivance, serving as a ready and efficient substitute for the pulleys, has been suggested by Dr. Fahnestock, of Pittsburgh. It consists in the use of a thin but strong rope, from four to eight strands of which are passed under the extending band, and doubled upon themselves. The free extremities are then drawn tightly, and secured

to a staple in the wall. A stick is next carried across the centre of the strands, and revolved upon its axis as a double lever. In this manner a single assistant may furnish any amount of power that may be necessary for gradually and steadily overcoming muscular action, while the surgeon himself attends to the dislocated bone. The annexed cut, fig. 638, affords a good illustration of the apparatus applied to the subject.

Fig. 638.

Fahnestock's Method of Extension and Counterextension.

Another instrument of great power is the dislocation-tourniquet, fig. 639, of Mr. Bloxam, of London, which, although it acts upon the same principle as the multiplying pulleys, is a more convenient as well as a safer contrivance capable of affording great aid in drawing the bone into its natural position in cases of unusual muscular resistance.

Fig. 639.

Bloxam's Dislocation-Tourniquet.

Of the surgical adjuster of Dr. Jarvis little need be said here. I have never employed it in recent dislocations, and in the repeated trials which I have made with it in those of somewhat long standing it has not been my fortune to meet with any marked success. It is an instrument of extraordinary power, and should, therefore, be used with great care and discretion. In the hands of its ingenious inventor it has doubtless been productive of benefit. Fig. 640 represents the adjuster as applied for the reduction of a dislocation of the hip-joint.

As the resistance of the muscles is one of the chief barriers to the reduction of dislocations, means, to which the term auxiliary is applied, are generally at once resorted to with a view to its counteraction. These means are both local and constitutional, and are particularly necessary in strong, robust individuals. The most efficient remedies of this class, formerly at the disposal of the surgeon, were copious blood-letting, usually carried to syncope, nauseating doses of tartar emetic, the warm bath, and the liberal use of anodynes. Sometimes the disgusting practice of intoxication by alcoholic liquor was pursued; and Dr. Physick occasionally advised the smoking of tobacco to bring about the desired relaxation. Since the introduction of chloroform and ether nearly all such means have become obsolete, these articles having very properly taken their place. Even bleeding is now seldom necessary, except occasionally where, from

excessive muscularity of the patient, unusual difficulty is expected, or where, from the injury sustained by the soft parts, it is important to employ at once active measures for preventing excessive inflammation. Tartar emetic, the warm bath, and tobacco enemas have justly been proscribed. The patient is anæsthetized in the usual manner, and all manipulation is withheld until the system is completely relaxed and the mind rendered unconscious, when the operation is at once proceeded with, the action of the remedy being maintained until the object is accomplished. I have pursued this practice in ever case of dislocation that has fallen under my notice during the last thirty years, and have every reason to be satisfied with the result.

Fig. 640.
Jarvis's Adjuster, applied for the Reduction of a Dislocation of the Hip-joint.

A surgeon, called to a case of dislocation immediately after its occurrence, may occasionally succeed in effecting replacement by taking advantage of the faint and relaxed state in which he finds the patient from the shock he has sustained. Or he may succeed by diverting his attention, either by engaging him in conversation, or by a sudden expression of surprise, while he makes a forcible attempt at reduction. The mere idea of pain is generally sufficient to excite the muscles to spasmodic action, so as to oppose the efforts at restoration. It was, therefore, formerly a matter of great consequence to prevent this by a playful remark, an impertinent question, or an angry reply, designed to distract the attention of the sufferer, and to throw the muscles off their guard. Dupuytren is reported, upon one occasion, to have employed a similar, although less polite, expedient. Having been called to a lady of rank on account of a dislocation of the shoulder, he was for a long time foiled in his efforts; the assistants pulled, he pushed and pressed, and she shrieked and offered every possible resistance. His temper became ruffled, and he tried in vain to distract her attention. At last, said he, "Madam I have repeatedly asked you how this accident happened, and you have as repeatedly deceived me; you have not informed me that you had been drunk." The woman, shocked at the remark, indignantly asked, "Who told you so?" "Your son, madam." The poor patient was stupefied, all the muscles became instantly relaxed, and in a moment the luxation was reduced.

When an anæsthetic is used, the surgeon effects the reduction either by his own personal efforts, or he employs such aids as the exigencies of the case may seem to require. When the extension and counterextension have been maintained for some time, bringing thus the head of the displaced bone gradually nearer and nearer to its socket, he should grasp the part firmly, and thus assist in lifting it into its natural position. Or he may accomplish this by means of a band or fillet thrown across his neck and shoulder, while he makes strong and steady pressure against the head of the bone, pushing it back in the direction of the luxation or towards its fellow. In many cases the reduction will be facilitated if, at the moment the bone approaches its socket, the limb is rotated upon its axis, carried towards the body, or drawn over the opposite limb. When the replacement is

unusually troublesome, the ingenious surgeon will not fail to employ all kinds of expedients and stratagems to accomplish his object, rather than abandon the patient to his fate with a useless limb. It is now well ascertained that almost every recent simple dislocation may be effectually and expeditiously reduced by manipulation alone, especially if the patient is completely anæsthetized. Difficulty will be likely to occur only, or chiefly, when the head of the bone has slipped through a very narrow opening in the connecting ligament, grasping the bone with extraordinary firmness, and so impeding its return to its proper position.

The restoration of the dislocated bone is indicated by the reëstablishment of the shape and motion of the joint; by a snap or noise heard at the moment of the reduction, but which is always very faint when the patient has been anæsthetized; and by a great and sudden diminution of pain.

Finally, it is always very desirable to effect replacement as speedily as possible, even although there should be considerable inflammation and swelling, and, consequently, a probability of inflicting some pain; for it is much better to do this than to subject the patient to the risk of having, by the delay, an irreducible dislocation, of which there must alway be some apprehension, especially when the injury involves a ginglymoid articulation. An exception to this rule must, of course, be made when the joint is excessively swollen and tender, when a few days may be profitably spent in the employment of leeches and saturnine and anodyne lotions, antimonials, and other means, until the inflammation is sufficiently reduced to render the parts tolerant of the necessary manipulation.

In obstinate cases of dislocation, rendered so by the manner in which the bones are interlocked with each other, and in which the muscles passing over them are stretched like tense cords, the reduction is sometimes greatly facilitated by subcutaneous tenotomy. The expedient is particularly valuable in dislocations of the tarsal joints, but it may also be advantageously employed in displacement of the larger articulations, especially in those of long standing. The operation has often been successfully performed, without, so far as I am aware, having been followed by any bad results. Care must, of course, be taken to avoid interference with important structures.

After-treatment.—When the reduction is completed, measures must be adopted, first, to prevent a recurrence of the accident, and, next, to limit inflammation, more or less of which must necessarily take place after every injury of this kind, however simple. The former of these objects is accomplished by appropriate bandages, or bandages and splints, with rest in the recumbent posture, especially if the injury be seated in the lower limbs; in dislocations, on the contrary, of the upper extremity, the arm should be suspended in a sling, and the patient, after a few days, be permitted to walk about in the open air. Inflammatory accession is met by the usual antiphlogistic remedies, both constitutional and topical, among the latter of which evaporating lotions, as alcohol and water, and solutions of acetate of lead, along with laudanum, are the best, and they will generally be found most agreeable and beneficial, at least during the first forty-eight hours, if applied warm. The joint, if favorably situated, is supported with a roller to assist in moderating effusion and swelling. Its effects, however, must be carefully watched, otherwise it may occasion undue constriction. Pain is subdued with full doses of morphia.

Finally, every means should be employed to guard against the occurrence of ankylosis. With this view passive motion should be instituted as soon as the inflammatory symptoms have abated, and repeated, steadily and perseveringly, at first once, and afterwards twice, or even thrice, a day, until the functions of the joint are perfectly reëstablished; an object which can seldom be attained, in any case, under several months, and in some, indeed, not under six, ten, or twelve, depending upon the nature of the joint, the extent of the injury, the character of the treatment, and, above all, the coöperation of the patient, whose conduct has often much more to do with the production of a stiff and useless joint than that of his surgeon. After the more prominent inflammatory symptoms have disappeared, the absorption of effused fluids should be promoted by soap liniment, or moderately stimulating embrocations, followed, in due time, by the cold douche, dry frictions, massage or shampooing.

3. COMPLICATED DISLOCATIONS.

A complicated luxation, as stated elsewhere, is one in which the displacement is accompanied by a fracture, the rupture of an important vessel or nerve, a violent contusion, or a wound communicating with the cavity of the articulation, or extending deeply among the tissues in its neighborhood. Not unfrequently several of these lesions coexist, thus materially increasing the gravity of the case, and the difficulty of managing it.

Although such an accident may occur in any of the articulations, it is by far more frequently met with in those of the elbow, knee, and ankle than in any other, for the reason, probably, that the heads of the bones are less protected there by muscles, and also that they are more sharp or angular, than in the orbicular joints. Hence, when the injury is unusually violent, the articular extremities, losing their ligamentous connections, are apt to be impelled with so much force against the soft parts as to lacerate them from within outwards, dividing muscles, tendons, fasciæ, vessels, nerves, and integument, and, perhaps, protruding several inches beyond the external wound; or, the vulnerating body, impinging forcibly against the external surface, may commit the mischief from without inwards, the bones being comparatively passive until the moment they are struck, when they, in their turn, may inflict additional injury upon the structures beyond where the projectile does not penetrate. In the great majority of instances, at least in civil life, the lesion is caused by falls, blows, or kicks; in military practice, by gunshot injury.

Compound dislocations, as they are commonly called, that is, dislocations in which there is a wound opening into a joint, are very rare in comparison with simple. Thus, of 94 cases of dislocations, reported by Dr. Norris as having occurred in the Pennsylvania Hospital, only 2 were compound; and of 166 cases collected by Professor Hamilton, only 8 were of this description.

The *symptoms* of complicated dislocations are usually so characteristic as not to require any formal description. In general, there will be more or less distortion of the joint, inability of motion, discharge of synovial fluid, and shortening of the corresponding limb, with contusion, discoloration, and ecchymosis of the soft parts. In case there is a wound, the end of the bone not unfrequently protrudes at the external opening; sometimes to a distance of an inch or more. Crepitation will be likely to be present when the dislocation is complicated with fracture. Great numbness and partial paralysis will indicate lesion of an important nerve; while coldness of the extremity, with absence of pulsation in its distal portion, and copious extravasation of blood, will be denotive of serious injury of the principal artery.

A complicated luxation, as the name implies, is always a grave accident, often jeopardizing the safety alike of limb and life. The resulting inflammation is generally extremely violent, and is peculiarly prone to lead to abscess, erysipelas, and pyemia, especially in persons of intemperate habits, or of a dilapidated system. Under such circumstances, and sometimes even when the health was most perfect immediately before the injury, the constitutional disturbance is usually very great, delirium sets in early, and the parts are soon seized with gangrene. The danger of mortification will necessarily always be proportionately great when there has been a division of an important vessel or nerve, interrupting circulation and innervation; pyemia will be most likely to occur when there has been excessive shock, and necrosis when the protruded or exposed bone has been stripped of periosteum, splintered, or covered with dirt. But the danger to limb and life is not limited to the primary effects of the injury; often, after an attempt has been made to save the parts, the surgeon is chagrined to find that all his efforts have been unavailing, that the patient is gradually worn out by hectic irritation and profuse discharge, and that amputation, now performed as a dernier resort, hardly holds out a single prospect of cure. A guarded prognosis, then, is becoming in every case of complicated dislocation, however apparently insignificant.

Treatment.—Much of our success in these accidents will depend upon the promptness and efficiency of our treatment, or the manner in which the parts are managed during and after the reduction, which should always be effected as speedily as possible, and with as much care and gentleness as the case will admit of, the patient being fully anaesthetized. If any wound exist, the edges must be brought accurately together with adhesive plaster, aided, if necessary, by suture, and coated with collodion to exclude the air. Or, Mr. Lister's antiseptic dressing, described elsewhere, may be used; for, although there is every reason to believe that its efficacy has been much exaggerated, it, nevertheless, possesses a certain value as a " protective," and is, therefore, deserving of a fair trial, the more especially as it is not likely, if properly applied, to do any harm.

Any loose splinters of bone that may be present in these accidents should at once be removed, while any that are sufficiently adherent to render it probable that, if left, they will reunite should not be interfered with. The fingers and forceps are the best instruments for performing the operation. If the end of the bone protrude at the wound, it must be promptly restored to its natural position, any dirt that may cover it having previously been picked away, or removed with the syringe. If it be girt by the integument, so as to render the reduction impracticable, a circumstance, however, which must be

extremely rare, the opening must be carefully enlarged with the probe-pointed bistoury; and a similar practice should be followed when the wound is too small to admit of the easy extraction of loose fragments. If the end of the bone is very sharp, angular, or denuded of periosteum, it should be cut off with the saw or pliers, but such a step should only be taken after the most thorough conviction of its imperative necessity; for the same rule applies here as in the soft parts, to save all we can, and sacrifice nothing improperly. I can hardly conceive of a case where it would be necessary to remove the end of a dislocated bone simply because it protrudes at a wound. If the patient is completely relaxed by anæsthesia, extension and counterextension, with judicious coaptative pressure, could not fail to effect restoration, even when the bone is very tightly girt.

When ordinary means fail to overcome the resistance of the muscles, tenotomy may be employed, as originally practised by Mr. William Hey, of Leeds, in a case of compound dislocation of the ankle, and since repeated upon other joints by Dieffenbach and other surgeons.

Finally, when the luxation is complicated with fracture, the rule is to reduce the former before the latter is permanently set, for the reason that, if the restoration of the joint be postponed until the broken bone is repaired, it will often be impossible to effect it. Besides, the union might be destroyed under the effort. Under such circumstances, the reduction of the luxation is always greatly facilitated by putting up the fracture firmly in splints, as a longer and better average is thus secured.

The reduction having been effected, the joint and corresponding limb are to be enveloped in a bandage—that of Scultetus being passed around the wounded part—and placed securely in splints, or, what is preferable, in a wire case, or wooden box, in order to keep it perfectly at rest, and in as easy a position as possible. Pain and inflammation are relieved by the usual remedies; and it is here that anodynes will be likely to display their happiest effects, both in allaying suffering and in preventing serious constitutional disturbance. Antiphlogistics must be employed warily, with due reference to the effects of shock, long confinement, and copious drainage. In a word, the patient must not be purged and bled simply because he has a compound dislocation; on the contrary, such measures, if used at all, must be used with the greatest possible caution. The diet must be rigidly adapted to the exigencies of the case; as in all other severe injuries, it should be nutritious rather than otherwise, and instances will not unfrequently arise where it should be decidedly so from the very commencement of the treatment. The enfeebled patient will often be immensely benefited by the addition of milk punch, whiskey, ale, or porter, especially if he is accustomed to the habitual use of any of these articles. Quinine and iron will materially aid recovery in the event of suppuration, erysipelas, or pyæmia.

The affected parts are handled as little and as gently as possible; all officious interference is refrained from; the secretions are removed from time to time with the sponge, and fetor is allayed with chloralum or permanganate of potassium. In case of wound, or much discharge, the limb should be surrounded with bran, for the threefold purpose of maintaining equable pressure, absorbing the secretions, and affording a comfortable bed for the parts to rest upon, with the additional advantage, in hot weather, of preventing the formation of maggots.

Concerning the propriety of amputation, the same general rules are applicable as in complicated fractures, a subject duly discussed under that head. The following summary, however, respecting the operation, will not be out of place here. The reasons for immediate amputation are, first, the excessive contusion and laceration of the soft parts; secondly, the rupture of the principal artery or nerve of the limb, attended with other serious injury; thirdly, an extremely shattered state of the bones; fourthly, free exposure of a large joint; and, lastly, the advanced age, depraved habits, or ill health of the patient. Secondary amputation may be required, when, after an attempt has been made to save the limb, gangrene has taken place, or life is assailed by exhausting suppuration, consequent upon extensive disease of the soft parts, the joint, or bones, or of all these structures together. Very great or irremediable deformity of the limb, standing in the way of its usefulness, is also a just cause for amputation.

Instead of amputation, in some of the above cases, excision may occasionally be advantageously employed, either primarily or secondarily. The primary operation is particularly indicated in dislocations complicated with a shattered and comminuted condition of the head of the displaced bone, and has been so often performed beneficially that it may now be regarded as one of the established proceedings in surgery. Its greatest success has been obtained in compound luxations of the shoulder-joint. Even when there is no fracture of the head of the dislocated bone, but simply extensive laceration of the liga-

ments, completely detaching the parts from each other, it is questionable whether, in many cases, excision would not be the more expedient practice.

Secondary resection may be employed in caries, or caries and necrosis, of the ends of the bone, coming on after a fruitless attempt to save the parts.

4. CHRONIC, OLD, OR NEGLECTED DISLOCATIONS.

The subject of chronic, old, or neglected luxations has not received the attention which its importance merits. The morbid anatomy of these accidents is still imperfectly understood, no connected body of facts illustrative of it having yet been published, and it is to be feared that their treatment is seldom guided by sound scientific principles. They constitute a class of cases which almost every surgeon approaches with doubts and misgivings, being anxious to do something for the patient's relief, and yet afraid the interference should produce serious, if not irreparable, mischief. I candidly confess that I have always shared these feelings, and that I have never had charge of an old or neglected dislocation without a strong secret wish that it had fallen into other hands, such have usually been my disappointment and the anxiety attendant upon my efforts at reduction. The risk of rupturing an important vessel, perhaps the main artery of a limb, of breaking a bone, or of exciting extensive suppuration in the parts around the affected joint, with the more remote chance of inducing pyemia, is well calculated to cause one to hesitate before he enters upon an enterprise so fraught with unpleasant consequences.

The blood that is effused in dislocations, unless unusually abundant, is generally very soon absorbed, as after other accidents involving subcutaneous hemorrhage. On this account it is very seldom that an opportunity is afforded of meeting with any in chronic cases; it is only now and then that a small clot or stratum, decolorized, and partially organized, is seen, and even this is almost always eventually carried off. The inflammation consequent upon the lesion is constantly followed by a deposit of plastic matter, both in and around the joint, filling up the socket of the bone, and infiltrating the connective tissue, muscles, and other structures in the neighborhood. More or less of this substance is also effused around the displaced head, where it is gradually organized, and at length converted into an adventitious capsule, of a pale-grayish aspect, and of a dense, fibroid texture, not unlike the original capsule, with which it generally communicates by one or more openings, and which, by degrees, becomes wasted and attenuated from want of use. The muscles, in great measure deprived of their functions, are transformed into pale, rigid, contracted bands, which, in time, often undergo the fatty degeneration. The periosteum, near the joint, is usually somewhat thickened, and occasionally even studded with os-

Fig. 641.

Old Dislocation of the Hip, a new Acetabulum being formed, while the Original one is but little Changed.

seous stalactites. The cartilage of the affected socket is generally partially absorbed, or more or less changed in its appearance, texture, and consistence, while that which invests the head of the bone exhibits a rough, scabrous aspect, being thickened at one point and atrophied at another, the osseous substance itself often becoming hard and sometimes even eburnized. Few opportunities have occurred of observing the condition of the vessels and nerves in ancient dislocations; in the cases in which this has been noticed, the former were found to be preternaturally flexuous, to accommodate themselves to the displaced bone, and the latter somewhat attenuated, but otherwise sound.

In those cases in which the displaced head enjoys a good deal of freedom, it generally forms for itself a sort of socket, as in fig. 641, most commonly in a neighboring bone, but sometimes in the substance of a muscle, or partly in the one, and partly in the other. This socket, however, although it may admit of considerable motion, is a very imperfect type of the original, as is also the new ligamentous tissue by which it is surrounded.

In addition to the changes now described, relating exclusively to the articular struc-

tures and to the parts immediately around, changes which are usually the more conspicu-
ous in proportion to the duration of the dislocation, it will be found that the whole limb
below the seat of the injury, and sometimes even for some distance above it, has a
shrunken and withered appearance, its muscles being thin, flabby, and wasted, and its tem-
perature materially diminished.   In many cases it is affected with rheumatic or neuralgic
pains, subject to aggravation with every change of the weather and with every disorder of
the general health.   The motion of the new joint is necessarily much restricted, and is
often performed with a peculiar grating noise and sensation, caused by the roughened state
of the contiguous surfaces, and the entire absence of synovial fluid.   When all motion is
lost, the joint gradually undergoes complete bony ankylosis.

Is it possible for the head of a bone, long dislocated, to undergo such an amount of
absorption as to give rise, when restored to its proper place, to shortening of the affected
limb?   I should unhesitatingly answer this question affirmatively, with the proviso, how-
ever, that the corresponding articular cavity retains its natural shape and depth.   In lux-
ation of the head of the femur, for example, the shortening of the thigh might, from this
cause, under peculiar circumstances, probably be from half an inch to eight, nine, or even
ten lines.   In discussing this question, it should be remembered that there is occasionally,
if indeed not frequently, a natural disparity in the length of the two limbs, both upper
and lower, amounting, it may be, to nearly one inch.

It has long been a question with surgeons at what period after the occurrence of a dis-
location it should be considered as impracticable to effect reduction, and the question, as
might have been expected, has been differently answered by different observers, and by
the same observers for different joints.   Thus, Sir Astley Cooper, who has always been
regarded as a leading authority upon the subject, thought that three months for the shoul-
der, and eight weeks for the hip, might be set down as the limit, beyond which any efforts
of this kind, except in persons of very lax fibre or advanced age, would be highly impru-
dent; an opinion which accords so well with general experience, as, in my judgment, to
entitle it to be considered as a law.   It cannot be denied that this law has exceptions,
but this only serves the more fully to establish its validity.   Thus, in relation to at least
one of the joints in question, that of the shoulder, a considerable number of cases have
been reported of reduction at from four to seven months after the receipt of the injury.
Indeed, Dr. Nathan Smith, of New Haven, met with one in which he succeeded com-
pletely nearly one year after the accident.   Examples of reduction of dislocations of the
hip-joint from three to six months' standing have also occurred, although it will be found,
upon careful inquiry, that their number is exceedingly small.

For the ginglymoid articulations the period is still more limited, although, in this
respect, it varies a good deal among themselves.   In the elbow-joint, the best type of the
ginglymoid class, I have found, in a very considerable number of cases, that any attempts
at reduction, however perseveringly or judiciously continued, generally prove completely
abortive after the third week.   The differences in the reducibility of dislocations of dif-
ferent articulations are altogether due to peculiarities of structure and to the amount of
inflammation consequent upon the injury.   The surfaces of the orbicular joints are com-
paratively smooth and simple, and their displacements are seldom followed by much inflam-
mation; the reverse in both particulars being true in regard to the ginglymoid joints.

Evidently, then, every luxation must rest, so to speak, upon its own merits, so far as
the question of its restoration is concerned; for, as just stated, while one joint becomes
irreducible in a fortnight or a month, another, differently constructed, may remain redu-
cible eight weeks, or even a much longer period.   A far better rule by which to decide
this question is to judge by the extent of motion of the affected bones, the previous attempts
at replacement, and the degree of inflammation consequent upon the injury.   If the joint
is very stiff and tender, if the luxated head has contracted firm adhesions, involving, per-
haps, a large artery, or some other important structure, and if, in addition to this, there
is reason to believe that the socket is filled up with new matter, any effort at reduction
would not only prove abortive, but might be followed by very serious accidents, jeopard-
ing limb and life.   Cases in which severe injury and even death were the consequences
of long-continued and violent attempts at reduction have happened to surgeons of great
experience and eminence, and should serve as warnings against the employment of undue
force where the prospect of success is at all doubtful.

The conduct to be observed in the reduction of chronic dislocations resolves itself into a
few simple rules.   In the first place, it is necessary, as an important preliminary, to pre-
pare the part, as well as the constitution, for the operation, by the systematic movement
of the joint, and by light diet and purgatives, aided, if the person is at all strong and ple-

thorie, by at least one large bleeding. The object of this depletion is not so much to weaken the muscles as to lessen the risk of severe inflammation and the formation of abscesses. The motion of the joint is intended to break up any abnormal adhesions that the bone may have contracted with the surrounding tissues, and should be conducted with great care and gentleness, the corresponding limb being carried about in different directions, flexed, extended, depressed, elevated, adducted, abducted, rotated, and circumducted; the operation should not be performed, at first, oftener than once a day, but by degrees it may be repeated every twelve hours, and it should be steadily continued for at least a fortnight, free use being made all along of evaporating and sorbefacient lotions, with minute doses of mercury, to promote the absorption of effused plasma. Continuous extension, as a preliminary step to more strenuous efforts for promoting the reduction of chronic dislocations, has lately been recommended, and is deserving of consideration, especially in the more simple forms of such accidents.

This preliminary treatment having been attended to, and the patient being thoroughly anæsthetized, the extension and counterextension are conducted in the usual manner, only with more care and patience, and with an additional number of assistants. The object is not, as in recent luxations, to fatigue the muscles, but to extend and stretch their fibres, shortened, hard, and tense from long-continued disease and inflammatory irritation. In no event should the surgeon employ violent or forcible measures, because such a procedure would be sure not only to increase the resistance, and, as a necessary result, the difficulties of the reduction, but be very likely to cause dangerous laceration of the soft parts, and secondary mischief. If the operation fail, it must not be too soon repeated, and in the mean time the suffering joint must be well supported and fomented. The rupture of an important artery, as, for examp'e, the axillary in dislocation of the shoulder, will be denoted by a rapid effusion of blood into the connecting tissues, discoloration of the integument, and cessation of pulsation in the distal portion of the limb. The proper remedy, in such an event, is immediate ligation of the affected vessel, and the avoidance, of course, of further interference. Should fracture occur, the operation must also at once be suspended, and the case treated upon general principles.

Dr. H. G. Davis, of New York, a few years ago, called attention to the value of continuous elastic extension, by means of India-rubber bands, in the treatment of chronic luxations, and he asserts that he has met, in several cases of this kind, with remarkable success. I am not sure that others have been equally fortunate. Dieffenbach, of Berlin, many years ago, proposed, as a measure of overcoming the resistance, under such circumstances, the subcutaneous division of the muscles concerned in opposing the restoration of the bone, and such an operation has repeatedly been performed, although rarely with the advantages that had been anticipated. I have myself occasionally employed it, but never with any decided benefit. The great objection to the procedure is the danger of wounding important structures, especially large vessels and nerves, which are very often greatly displaced, and which, if injured, might occasion serious consequences. No one, therefore, should undertake such an operation unless he has the clearest possible conceptions of the anatomy of the parts, and is fully prepared to meet any emergency that his knife may produce.

When the head of a displaced bone is immovably fixed in its new relations, and the corresponding limb is thereby rendered completely useless, an attempt should be made by the subcutaneous division of its neck to form an artificial joint. If the operation fail, the only thing that remains to be done is excision of the head, a procedure indispensably necessary when the bone presses upon large nerves, as, for example, in certain forms of luxation of the shoulder-joint.

5. CONGENITAL DISLOCATIONS.

There are certain dislocations which exist at birth, and which are, therefore, denominated congenital. Their occasional occurrence, recognized at an early period of the profession, has been satisfactorily established by a number of modern observers, especially by Chaussier, Paletta, Dupuytren, Breschet, Pravaz, R. W. Smith, Guérin, and Carnochan.

Different joints are liable to this variety of luxation, but its occurrence is by far most common in those of the hip, wrist, and shoulder. The lesion, although generally single, is sometimes double, existing simultaneously in the two opposite articulations. Occasionally it occurs in different joints in the same subject, as, for instance, in the shoulder and wrist, or in one of these joints and in that of the hip. Both sexes are liable to it, but by no

means in an equal degree, observation having shown that females suffer much more frequently than males. Instances are recorded in which the affection appeared in a number of successive generations, and also in several members of the same family.

The *causes* of congenital dislocations have excited much attention, as well as a great deal of controversy, without eliciting any positive results. The various theories that have been advanced in explanation of this vexed subject may be arranged under the following heads:—1st, external violence inflicted upon the fœtus; 2dly, disease of the articulations; 3dly, arrest of development.

1st. There can be no doubt that undue force exerted upon the fœtus, whether from without, as when the mother receives a fall or blow upon the abdomen, or from inordinate contraction of the uterus, is capable of inducing partial dislocation of the joints, or, at all events, such a state of the articulating surfaces as to predispose them strongly to its occurrence. It is well ascertained that external violence is capable of producing fractures of the fœtal bones; I have myself met with several remarkable examples of this kind, and Chaussier has recorded a case in which this lesion coexisted with congenital luxation of the hip and shoulder joints. It is extremely probable that a deficiency of the amniotic liquor may predispose to this occurrence, by enabling the womb to exert its contractile force more readily and fully upon the fœtus, thus forcing the articulating surfaces away from each other at a time when they are too imperfectly developed to resist such pressure, especially if frequently repeated. A theory of the formation of clubfoot, which is probably nothing originally but a partial displacement of the tarsal joints, has been founded upon this supposed contractile power of the uterus, and of its injurious influence upon the fœtus. Finally, it is not improbable that what is termed a congenital luxation may be occasionally produced by violence inflicted upon certain joints during delivery, in rude and forcible attempts to bring away the extremities.

2d. The second theory rests upon the idea that the lesion depends upon congenital disease of the joints, inducing relaxation of the ligaments, and so favoring the action of the muscles in separating the articular surfaces, and interfering with their development. Children in the womb are, as is well known, liable to numerous affections, some of them of a highly inflammatory character, terminating at one time in death, and at another in serious and irremediable deformity. Of these affections, synovitis is one, and it is probable that it generally has a gouty, rheumatic, or syphilitic origin.

3d. The theory of an arrest of development has many advocates, both in regard to the origin of this and other affections; but what do we know of it? Certainly nothing beyond the fact that it is expressive of the imperfect growth of a part, and of the concomitant deformity; it affords no clue whatever to the nature of the causes, either remote or proximate, that induced it. The fault may exist in the germ, or it may be superadded to it after conception, in consequence of some intrinsic defect, or as a result of the operation of causes acting through the mother.

The *pathological* changes accompanying this lesion are numerous and diversified. In the first place, the dislocated articular extremities are generally deprived, in part, if not entirely, of their natural shape and structure; they are rounded off, divested of synovial membrane and cartilage, atrophied, and otherwise altered. The deepest cavity, as, for instance, the cotyloid, often completely disappears, not by being filled up with plastic matter, as in traumatic luxation, but by the absorption of its component elements. Very frequently the displaced bone forms a new socket, generally superficial, but quite sufficient for the amount of motion to which it is restricted. The ligaments are elongated and relaxed, thin, ribbon-shaped, partially wasted, or completely destroyed; occasionally, however, instead of being stretched and attenuated, they are very short, tense, and strong, obviously from interstitial deposits. The surrounding muscles are either pale, wasted, and partially transformed into fatty matter, or they are unnaturally large and stout, from the increased exercise devolved upon them by the dislocated bone.

The *symptoms* of congenital dislocation are characteristic. The affection, manifesting itself in various kinds of deformity, is noticed at, or soon after, birth, having commenced without any apparent violence; it is unattended with pain, or, if pain is present, it is much less than in the traumatic form of dislocation; the swelling also is inconsiderable, if, indeed, there is any at all; the head of the bone can be felt in its abnormal position, and the portion of the limb connected with it is generally singularly distorted, being changed in its axis, flexed, extended, or twisted. Motion is either much impeded, or too free; the affected member is commonly somewhat shortened, and more or less attenuated, from the wasted condition of its muscles. By extension and counterextension the displaced surfaces may generally be easily restored to their natural position but the moment

they are discontinued they resume their former condition. This is practicable, however, only in the younger class of subjects; in old cases, reduction is always proportionately difficult, indeed, often impossible. The deformity invariably increases with age, and is sure to be followed by an arrest of growth of the surrounding structures.

The *prognosis* is altogether unfavorable, and this is particularly true of the lesion when it is of long standing, as when the person has attained the age of puberty or of manhood, when no plan of treatment that has yet been devised can be of any material, if, indeed, of the slightest, avail, owing to the impossibility of effecting accurate adjustment of the articular surfaces, in consequence of the organic changes which they have undergone. Even under the most propitious circumstances, as it respects age and preservation of structure, the difficulties of effecting a permanent cure will generally be extremely great, well calculated to exhaust the patience both of the subject and the surgeon. The prognosis should, therefore, always be very guarded.

Treatment.—From what has been stated, it is evident that the sooner the treatment of this lesion is commenced the more likely will it be to be successful, or, if not altogether successful, productive of amelioration. The two leading indications obviously are to effect reduction, and to prevent a recurrence of the displacement. No difficulty is generally experienced in fulfilling the former, especially in very young and tender subjects; it is the latter that causes all the trouble, annoys the patient, and frets the surgeon. Various kinds of apparatus, much of it of a very complicated and expensive character, have been devised for retaining the parts in contact after their restoration; but it admits of doubt whether most of it could not advantageously be replaced by more simple means, such as ordinary splints, wire cases, and adhesive strips and rollers, which might be so applied as, in most cases, to answer the purpose most perfectly. Permanent extension and counterextension will be required when there is retraction of the dislocated bone. Long confinement, however, should always, if possible, be avoided, as it is of paramount importance to preserve the general health. The principal local remedies, worthy of attention, are the cold douche and friction with ammoniated and other liniments, together with direct support. If the patient is feeble and anemic, benefit will accrue from the use of tonics, as iron and quinine, a nutritious diet, and exercise in the open air.

When the reduction of these dislocations is opposed by the permanent contraction of the muscles, the only way to overcome the obstacle is tenotomy. The case should afterwards be treated upon the same principles as in clubfoot.

<center>SECT. XII.—DISLOCATIONS OF PARTICULAR JOINTS.</center>

<center>1. HEAD AND TRUNK.</center>

<center>DISLOCATIONS OF THE HYOID BONE.</center>

The possibility of a dislocation of this bone is fully attested by a number of well-authenticated examples. In 1848, Dr. Ripley, of South Carolina, read a paper upon the subject before the Medical Society of Paris, in which he described such an accident as having occurred in his own person; and Dr. Gibb, of London, has met with not less than four cases of it, all in the male sex. In one of these there was an occasional displacement of the left horn of the hyoid bone, the patient perceiving a sudden click in that part of the neck, and a sensation as if something were sticking in his throat. He at length died of phthisis, when it was ascertained that the thyro-hyoid articulation contained, besides a considerable quantity of clear fluid, a large sesamoid bone, the whole arrangement being such as to admit of an extraordinary amount of motion.

The reduction is effected by throwing the head backwards as far as possible, so as to put the muscles of the neck completely on the stretch, and then relaxing the lower jaw, at the same time that gentle pressure is made upon the displaced part. The bone, in the case of Dr. Ripley, always returned with a click.

<center>DISLOCATIONS OF THE JAW.</center>

The connection between the lower maxillary and temporal bones is established by a hinge-joint, each condyle of the former moving upon an interarticular cartilage, and being held in place by two ligaments. Luxation, therefore, can occur only in one direction, that is, forwards and downwards, the condyle slipping off the articular eminence of the

temporal bone into the zygomatic fossa, as in fig. 642. The coronoid process lies immediately below the malar bone, the temporal muscle and the ligaments of the jaw are unnaturally tense, and the interarticular fibro-cartilage is partially dragged from

Fig. 642.
Double Dislocation of the Lower Jaw.

its position, but retains its attachment to the condyle. The displacement is usually double, affecting both sides simultaneously, and is commonly produced by some sudden, spasmodic contraction of the muscles in yawning, laughing, vomiting, or convulsions. Dorsey has recorded the case of a woman who luxated her jaw in the act of scolding her husband. The accident has sometimes happened in an attempt to extract a tooth, to bite a large apple, or to crack a nut. Occasionally it arises from a blow, fall, or kick upon the chin, the mouth being widely opened at the moment, and the condyle advanced upon the articular eminence. In 1861 I saw a woman, twenty-nine years of age, a patient of Dr. Emile Fischer, who dislocated her jaw on both sides in an attempt, during an attack of delirium, to pull her tongue out of the mouth. Dr. H. C. McCarthy has communicated to me the particulars of the case of a woman, aged thirty-two years, in which it was occasioned in an epileptic fit. Dr. Guignier met with an instance consequent upon a laryngoscopic inspection.

Fig. 643.

Dislocation of the Lower Jaw.

More frequent in women than in men, and in middle-aged and delicate subjects than in the old and robust, it is extremely rare in young children, owing to the peculiar conformation of the body and branches of the jaw rendering the occurrence one of great difficulty. A case has been reported by Chassaignac in which, in a fall from a great height on the chin, one of the condyles of the jaw was driven through the temporal fossa into the skull.

The *symptoms* are generally characteristic. The mouth, as exhibited in fig. 643, is widely opened, and cannot possibly be closed; the chin is unusually prominent, and the lower line of teeth projects considerably beyond the upper; the saliva, increased in quantity, dribbles off involuntarily; deglutition and articulation are performed with great difficulty; the cheeks and temples are flattened, and, as it were, elongated; the coronoid process is easily distinguishable in the zygomatic fossa, especially if examined through the mouth; and, instead of the natural prominence formed by the condyle immediately in front of the ear, there is a distinct vacuity capable of receiving the end of the finger, although not without some effort, owing to the great tension of the integument. When the displacement has existed for some time, the symptoms will be less marked, but still sufficiently characteristic to prevent mistake, provided the surgeon informs himself fully of the history of the case and of the actual condition of the jaw and mouth. Notwithstanding this, a very ridiculous error has occasionally been committed, as in an instance which came under my observation in a middle-aged woman, who, in an attack of cholera, luxated the lower jaw, the accident being mistaken for tetanus. An error has occasionally been made after apoplexy attended with paralysis of the muscles of one side of the face.

When the luxation remains unreduced, the jaw, in time, partially regains its motion, the dental arches approaching each other, so that, eventually, the patient may even be able to masticate his food; speech and deglutition also improve; the saliva ceases to dribble; and much of the disagreeable deformity disappears.

The patient, during the *reduction*, may sit upon the floor or upon a low stool, his head being well supported by an assistant. The surgeon, standing in front, introduces his thumbs, carefully defended with the end of a napkin, into the mouth, as far back as pos-

sible upon the large grinders, while he places the fingers of each hand under the chin and base of the jaw. Using his thumbs as fulcrums, he forcibly depresses the back part of the jaw, to disengage the condyles from the zygomatic fossæ, and at the same moment elevates the chin with his fingers, thus converting the bone into a lever of the first kind. Or, instead of this, the thumbs being placed as before, the surgeon grasps the angles of the jaw with his fingers, when, the mouth being well opened, the slightest downward pressure will be sufficient to disengage the condyles, and so enable the temporal and masseter muscles to effect the reduction. Restoration is generally indicated by a loud snap, and the instant it is about to occur the surgeon quickly removes his thumbs from the teeth, lest, in the act of closure of the jaw, they be seriously injured by the suddenness and violence of the contraction of the muscles.

The reduction is always greatly facilitated by the use of anæsthesia, which, while it completely relaxes the muscles, obviates the necessity of removing the thumbs from the jaw as the bone is sliding noiselessly into its place.

A very simple and efficient method of reducing dislocations of the lower jaw was originally suggested by Nélaton. The patient being seated upon a chair, and the mouth widely opened, the surgeon, standing behind him, plants his thumbs upon the upper part of the nape of the neck, and then with the fingers pushes the jaw forwards by pressing against the prominence formed on each side of the cheek by the point of the coronoid process. A small amount of force generally suffices to effect the object, the condyles returning with a distinct snap. When the resistance is unusually great, the head may be supported by an assistant, or a band may be passed around it, in which the operator engages his fingers, while the thumbs, resting upon the cheeks, are made to bear upon the coronoid process from above downwards, and from before backwards.

The older surgeons were in the habit of reducing luxations of the lower jaw by placing between the molar teeth two pieces of cork or wood, which they used as fulcrums to depress the back part of the bone, while they raised the chin by means of a bandage. Another method, occasionally employed by them, consisted in pressing a stick against the lower grinders, so as to keep the jaws separated until the irritated and contracted muscles, overcome by fatigue, allowed the condyles to glide into their natural situation. In obstinate cases, I have occasionally accomplished the object after a failure of the ordinary methods, by reducing the dislocation, first, on one side, and then on the other, the success being evidently due to the removal of the tension of the muscles concerned in keeping the bone in its constrained position.

In unilateral displacement of this bone, the chin is thrown towards the opposite side; the parallelism of the front teeth is lost; the mouth is open, but less widely than in the double luxation; speech and deglutition are somewhat impeded; and the depression in front of the ear is perceptible only on the injured side. The reduction is effected upon the same principle as in the other form of the accident, with the difference that only one thumb is used. Tartra met with a case of unilateral dislocation of the jaw in a child only fifteen months old.

After both of these luxations, but especially the bilateral, the patient should for some time avoid opening his mouth, as the accident is extremely liable to recur from very slight causes. The safest plan, therefore, is to support the jaw with an appropriate bandage, as that, for example, used in fracture. During the first few weeks the nourishment should consist exclusively of slops and of other articles that do not require mastication.

When the dislocation is complicated with fracture of the jaw, the difficulty which is sometimes experienced in keeping the parts in place may generally be easily remedied by means of a mould of sheet lead. In the case of an elderly gentleman in whom this coincidence existed, and whom I attended along with Dr. W. Macpherson, this mode of dressing answered the object most admirably.

In neglected cases of this dislocation the reduction will generally be found to be very difficult even as early as the end of the third or fourth week. Occasionally, however, it will succeed after a much longer interval. Thus, Morley had a case at the thirty-fifth day; Spat at the fifty-eighth; Donovan at the ninety-eighth; Nélaton at the one hundred and fourteenth; Michon and Gosselin at the one hundred and thirtieth day, and Pollock one at the end of the fourth month. When the ordinary means fail, instead of abandoning the patient to his fate, the efforts at reduction should be aided by the subcutaneous section of the external pterygoid, masseter, and temporal muscles.

There is a rare species of displacement of the lower jaw, originally described by Sir

Astley Cooper under the name of *subluxation*, which, apparently, depends upon an unusual laxity of the ligaments, permitting the condyle to slip off the interarticular cartilage. It is most common in weak, delicate females, and is characterized by inability to close the mouth, with more or less pain, and a feeling of tension on the injured side. If the bone do not return of its own accord, as it generally will, replacement may easily be effected by drawing the jaw slightly forwards and downwards, so as to afford the condyle an opportunity of reinstating itself upon the interarticular cartilage.

A curious condition of the temporo-maxillary joints is occasionally met with, chiefly in young, feeble, anemic subjects, which, on account of the peculiar crackling, creaking, or snapping noise so constantly attendant upon it, is often a source of great annoyance and even mortification. Its immediate cause is a relaxed condition of the ligaments, which allows the condyles to mount upon the articular eminences when the jaw is depressed, and of their slipping back suddenly when it is elevated. There is generally a deficiency of synovial fluid, and the condyles not unfrequently form unsightly prominences under the skin, especially in thin, emaciated persons. The most suitable remedies are tonics, as iron and quinine, the cold shower-bath, electricity, exercise in the open air, and the application of a series of little blisters over the affected part. The jaw should be carefully protected during yawning.

A *congenital* dislocation of the lower jaw has been observed in a few cases. Mr. Robert W. Smith having been the first to describe such an accident, of which he has given, with great minuteness, the results of the dissection. The patient, an idiot from infancy, died at the age of thirty-eight. The luxation existed on the right side, which was remarkably deformed, having a singularly hollow appearance, which strikingly contrasted with that of the sound one, which was unusually full and plump. The extremity of the finger could readily be pressed between the posterior margin of the jaw and the external auditory canal, owing, as was found on dissection, to the absence of the condyle of the bone, which was, in fact, greatly atrophied nearly as far forward as the symphysis. There was no interarticular cartilage, or distinct capsular ligament; and both the masseter, pterygoid, and temporal muscles were much wasted. The temporal, malar, superior maxillary, and sphenoid bones were imperfectly developed, and the glenoid cavity existed merely in a rudimentary state.

DISLOCATIONS OF THE CLAVICLE.

Dislocation of the clavicle, compared with fracture of this bone, is extremely uncommon, there being probably fifty cases of the latter to one of the former. The cause of this remarkable difference is to be found in the exposed situation of the bone, and the great shortness and strength of its ligaments, which render it much more liable to yield in its continuity than at its articulations with the sternum and scapula. The displacement may occur at either joint, and several instances are recorded in which both were simultaneously affected.

1. The *sternal extremity* may be dislocated forwards, backwards, and upwards, the relative frequency of the accident being in the order here stated. Luxation downwards is rendered impossible by the resistance offered by the cartilage of the first rib.

Dislocation *forwards* is generally produced by injury inflicted upon the top of the shoulder, or by falls upon the elbow when the arm is separated from the trunk. The clavicle, being thus impelled violently forwards and inwards, completely ruptures the sterno-clavicular ligaments, and present itself, along with the interarticular cartilage, in front of the upper part of the sternum. The sterno-cleido-mastoid muscle is pushed down, and some of its inner fibres are occasionally lacerated, particularly when they take their origin unusually near the joint.

The signs are, a hard, circumscribed, incompressible tumor at the upper and anterior part of the sternum, a vacuity at the natural situation of the joint, unusual prominence of the inner portion of the sterno-cleido-mastoid muscle, depression of the shoulder, and inclination of the head towards the affected side. The most reliable evidence, however, of the nature of the accident, is derived from tracing the outline of the bone with the finger of one hand, while the shoulder is moved by grasping the elbow with the other, and by recollecting that in dislocation the bone retains its normal length, while in fracture it is materially shortened. The head of the clavicle overlaps the sternum, and is always, as in fig. 644, directed downwards, so as to enable the examiner readily to distinguish the articular surface from which it has been removed.

The reduction is effected easily enough, but unfortunately it is retained with so much difficulty that, despite the best directed efforts of the surgeon, hardly an instance recovers without some degree of deformity. Many years ago I had a case of this kind under my charge, which, notwithstanding the most vigilant care and attention, was as bad, as it respected the cure, at the end of three months, as it was on the day it happened. Since then I have met with several similar examples. The articular cavity of the sternum is so shallow, and the ligaments unite with so much difficulty, that it is almost impossible to keep the parts in apposition sufficiently well or long to obtain complete consolidation. Fortunately, however, this occurrence does not materially affect the movements of the shoulder, for experience has shown that these are very soon, in great degree, reëstablished. It is a matter, therefore, simply of deformity, not of utility.

Fig. 644.

Dislocation of the Sternal End of the Clavicle.

To reduce this luxation, one hand is placed, shut, in the axilla, while the other grasping the elbow, pushes up the humerus against the clavicle and scapula. The shoulder is next carried upwards, outwards, and backwards, in a direction opposite to that of its displacement, and the forearm brought forwards across the chest, so that the thumb and fingers shall rest upon the sound collar-bone. If by this manœuvre the articular surfaces do not resume their natural relations, the reduction should be promoted by pressing the luxated head of the clavicle slightly upwards and backwards. A wedge-shaped pad, with the thick end upwards, being placed in the axilla, the limb is firmly secured to the side and front of the chest by the ordinary immovable fracture apparatus, a stout, square compress being applied directly over the sterno-clavicular articulation. The dressing must be frequently inspected, with a view to its readjustment, and be worn, with great constancy and regularity, for at least three months.

Dislocation backwards is generally produced in an indirect manner by injury applied to the shoulder impelling the scapula and the outer extremity of the clavicle forwards. It may also be caused by a severe blow upon the inner end of the bone, by the body being crushed between two resisting objects, and by violent traction upon the upper extremity when the trunk is firmly fixed and inclined backwards. The distinctive sign is that the head of the clavicle is forced backwards, and that it can be felt behind the summit of the sternum, sometimes below, at other times above, the level of that bone. A vacuity exists at the natural situation of the joint, the shoulder is directed somewhat forwards, the arm hangs uselessly by the side, and there is generally considerable dyspnœa, with cerebral congestion, and difficulty of deglutition, from the pressure of the luxated bone upon the trachea, cervical vessels, and œsophagus. The ligaments are completely ruptured, and the sterno-cleido-mastoid muscle is partially separated from its sternal attachments.

The reduction is effected upon the same principles as in the dislocation forwards, the fist being placed in the axilla and used as a fulcrum, while the shoulder is pushed upwards, outwards, and well backwards, and retained in this position by an appropriate apparatus, of which a figure-of-8 bandage, with a long, thick, square compress between the shoulders, is one of the best. Whatever means, however, be employed, it will be found extremely difficult to keep the articular surfaces in apposition and to prevent deformity. When the reduction is unusually obstinate, as it sometimes is when the head of the bone is firmly wedged in behind the sternum, the knee should be placed between the shoulders, the affected one of which should then be drawn forcibly backwards and outwards, the arm being at the same time extended nearly at a right angle with the trunk.

This variety of dislocation is sometimes produced by deformity of the spine, allowing the shoulder to sink gradually forwards so as to push the head of the bone from the sternum. In a case of this kind reported by Mr. Davie, of England, the clavicle compressed the œsophagus so severely as to cause great difficulty in swallowing, and danger to life by starvation. As reduction was impracticable, the trouble was remedied by sawing off the sternal end of the bone about one inch from the articulation. The patient speedily recovered, and lived six years after the operation.

Luxation upwards is so extremely rare that many of the most experienced surgeons formerly doubted the possibility of its occurrence. The cases, however, that have been reported by Macfarlane, Baraduc, Malgaigne, and others, fully establish its claims to the
character of a distinct species. The accident generally results from violence inflicted upon the shoulder, as a blow or fall, driving the scapula downwards and inwards towards the chest, thus separating the bone from its connections, and forcing it upwards above the fourchette of the sternum. The symptoms are usually very characteristic. The bony tumor can be distinctly felt and seen in front of the trachea, where it is easily impressed by moving the corresponding arm; the shoulder, sunk forwards and downwards, approaches nearer to the median line than naturally; there is a remarkable interval between the clavicle and the cartilage of the first rib, amounting to from six to twelve lines; the sterno-cleido mastoid muscle is put upon the stretch; and there is a vacuity at the joint, as in the other forms of the accident. The reduction is very easily effected, simply by lifting the shoulder thoroughly away from the chest, at the same time that it is slightly elevated and inclined backwards, and pressure made directly upon the luxated head. Retention will be facilitated by placing a pad in the axilla, and supporting the elbow and forearm well with adhesive strips and bandages. The union is generally imperfect, but this does not materially weaken the functions of the limb.

2. The *acromio-clavicular* articulation is formed by the acromion process of the scapula and the outer extremity of the clavicle, by a species of arthrodia, the concave surface of the former being closely adapted to the convexity of the latter, and the union established by strong ligamentous bands. Admitting hardly of any motion, it can be dislocated only by external violence applied either directly to one or the other of the two bones, or indirectly through the arm and sternum. The accident is usually attended with severe contusion of the soft parts, and is seldom so thoroughly repaired as not to be followed by some degree of deformity, although the recovery of the motions of the limb is eventually sufficiently perfect for all useful purposes.

The scapular end of the clavicle may be thrown from its natural position in three different directions; upwards, above the acromion process, downwards and backwards, beneath this prominence, and downwards and forwards, under the coracoid process. Of these luxations, the first is by far the most frequent, both the others being extremely rare.

Fig. 645.

Dislocation of the Acromial End of the Clavicle.

In the dislocation *upwards*, the end of the clavicle, breaking away from its articular connections, is thrown up by the action of the trapezius muscle, or by the impelling force, so as to overlap the acromion process, as in fig. 645, and form a small, hard, round tumor immediately beneath the skin, which disappears upon raising the arm, but is reproduced the moment we let go our hold. The head is inclined towards the injured side, the limb hangs closely along the trunk, the shoulder looks as if it were somewhat flattened, and the patient is unable, without great pain and difficulty, to carry his hand to his mouth; in a word, the whole attitude of the body is nearly the same as in fracture of the clavicle. The accident is usually caused by a blow upon the shoulder, and the circumstance of the trunk being strongly impelled forwards promotes the luxation by increasing the strain. It may also be occasioned by a fall upon the elbow, and by a kick upon the acromion process. However induced, there is necessarily, in the complete form of the lesion, a rupture not only of the acromio-clavicular ligaments, but also of the ligaments connecting the clavicle with the coracoid process. In the incomplete luxation the latter always escape.

The clavicle will readily resume its natural position if the shoulders be pushed upwards and backwards, while the knee is interposed between them behind, as the patient sits upon a chair. To maintain it in this situation, the same apparatus and dressings must be used as in fracture of this bone, and in the sterno-clavicular luxations, already described. A thick pad, with the base directed upwards, is placed in the axilla, and the arm and forearm must be well secured to the chest. Direct pressure by means of a stout compress and piece of sheet lead should be made upon the acromio-clavicular junction, and confined by a broad strap extending round the corresponding elbow, and secured to the chest with buckles; or, if greater pressure be required, a Petit's tourniquet may be employed, as suggested by Laugier. In a case which I saw along with Professor W. H. Pancoast, in

an elderly gentleman, this plan answered admirably. Despite, however, of all the precaution, care, and skill of the surgeon, he will seldom be able to procure a good cure. I have seen cases of this description treated for months with the most determined effort to succeed, and yet at the end of this time it was impossible for the patient to move his arm without causing a relapse.

Dislocation *downwards*, appropriately named infraäcromial, is exceedingly uncommon, only a few cases of it having been reported. The fact is, although it was described by J. L. Petit, who believed it was more frequent than dislocation upwards, it has been almost entirely ignored by modern systematic writers. It has been alleged that the accident cannot happen without previous fracture of the coracoid process, a conjecture which has been satisfactorily disproved by experiments performed upon the dead subject.

The accident, in a few cases that have been carefully studied, has been the result of violence inflicted upon the shoulder, as a heavy blow, or a kick from a horse, attended with a rupture of the coraco-clavicular ligaments. The characteristic sign is the situation of the end of the clavicle beneath the acromion process, which is at the same time remarkably prominent, and somewhat nearer to the sternum than in the natural state. The shoulder is flattened, and the arm, applied close to the side, is incapable of voluntary motion. When the evidence is so distinct, error of diagnosis must be impossible. If any doubt, however, should arise, it may easily be dispelled by tracing the outline of the two bones as far forwards as their articulation; the finger, as it approaches this point, will at once detect the extraordinary prominence of the one, and the marked depression of the other, and so reveal the true nature of the accident.

The reduction is accomplished by pulling the shoulder outwards and backwards, while the knee rests against the dorsal portion of the spine, and the patient's elbow is carried across the chest, to afford greater relaxation to the muscles, and convert the humerus into a lever for acting more efficiently upon the acromion process. Retention is effected in the usual manner, with the additional precaution of preventing all motion of the inferior extremity of the scapula.

The dislocation *forwards and downwards*, beneath the coracoid process—the infra-coracoid form of the accident—is, like the preceding, very uncommon, a fall or blow upon the anterior surface of the shoulder being the cause by which it is ordinarily produced. The symptoms are characteristic. Besides the contusion and discoloration common to all such injuries, the acromion and coracoid processes are unusually prominent; the top of the scapula is strongly inclined downwards and forwards, and there is a marked depression in the natural situation of the clavicle, which, upon being traced with the finger, is found to be directed outwards and downwards, its extremity being actually lodged in the axilla. The arm may be moved in every direction, except upwards and inwards.

The reduction is easily effected. The chest being firmly fixed with a strong napkin, an assistant seizes the arm, and, converting it into a lever, uses it for pushing the scapula forcibly outwards and backwards, while the surgeon himself, grasping the clavicle, disengages it from its position beneath the coracoid process, and thus restores it to its natural situation. The retention is maintained by the usual apparatus.

Owing to the peculiar structure of the sterno-clavicular and acromio-clavicular joints, and the fact that their ligaments are always very badly ruptured in their dislocations, it is almost impossible to keep the parts in contact by any apparatus that can be used for the purpose. In view of this difficulty, I suggested, many years ago, the propriety of connecting the articular extremities with silver wire introduced subcutaneously, and allowed to remain, if not permanently, at all events, until firm reunion is established. I have never had occasion to perform the operation, but successful cases of it have been reported by the late Dr. Cooper, of San Francisco, and the late Dr. Hodgen, of St. Louis. Recently, several cases of these different forms of luxations of the clavicle have been successfully treated, among others one by Dr. Eastman, of Indianapolis, with the plaster jacket, applied in such a manner as to place the affected joint thoroughly at rest, and prevent thoracic respiration.

Double dislocation of this bone has been observed only in a few instances. One of these, reported by Porral, is said to have occurred under the care of Gerdy, in the St. Louis Hospital, at Paris. The accident was caused by a fall from a third-story window, upon the upper and back part of the shoulder. The symptoms were well marked, the acromial ends of the bone being luxated backwards and upwards, the sternal upwards and forwards. The treatment was by Desault's well-known, but now obsolete, apparatus, aided by large, graduated compresses over the affected joints. Under this dressing, the

outer extremity of the clavicle soon became firmly united, but the other continued obstinately displaced.

A similar case was reported by Morel-Lavellee, in 1859 ; and, in 1866, Dr. N. L. North, of Brooklyn, met with another, his patient being a lad, fourteen years of age, who, in a fall from a stool, was thrown forcibly backwards, receiving the whole weight of his body upon the posterior part of the left shoulder. The displacement was complete at both joints.

The collar-bone is occasionally dislocated as the result of a *congenital* vice, as in a case which I saw in a child three months old, otherwise perfectly healthy and well formed. The displacement may be double ; but in the instance under my care it was confined to the sterno-clavicular articulation, the clavicle projecting upwards and forwards in a very unseemly manner ; and, although the reduction could readily be effected, it was impossible to keep the parts in place by any contrivance that could be devised for the purpose.

DISLOCATIONS OF THE STERNUM.

Dislocations of the sternum are extremely rare, and must necessarily be the result of extraordinary violence. Hence, they are nearly always complicated with serious lesion of the soft parts, and fracture of the ribs, spine, clavicle, or even of the sternum itself. The accident has hitherto been noticed only between the first and second pieces, the latter of which was always thrown in front of the other, no instance having yet been witnessed in which the displacement occurred in the opposite direction. In 10 cases collected by Malgaigne the dislocation was occasioned either by direct violence, as a blow or severe pressure, or by a fall from a considerable height, in which the spine was bent forcibly forwards. Of these cases, 5 terminated fatally from other injuries. Of 13 cases collected by Professor Brinton, of this city, including 1 observed by himself, 7 died and 6 recovered. The immediate cause of death in 6 of the cases was fracture of the vertebral column. When the luxation is simple, no serious consequences are to be apprehended. The most reliable symptom is deformity, attended with pain, dyspnœa, and a creaking sound during respiration. The only accident with which it is liable to be confounded is fracture of the sternum. The reduction is not always practicable. When the overlapping is considerable, the best plan is to extend the patient's body over a few large bolsters and to push the second piece forcibly downwards and backwards.

A few cases have been recorded of dislocation of the ensiform cartilage from blows or falls upon the epigastrium. The accident is generally attended with pain in the stomach, dyspnœa, and obstinate vomiting. Reduction is effected by extension and pressure. In one instance an incision was made on one side of the depressed cartilage, through the peritoneum, and restoration accomplished by means of an elevator.

An example of congenital dislocation of the ensiform cartilage, caused by a fall during the fifth month of pregnancy, has been reported by Seger.

DISLOCATIONS OF THE SCAPULA.

Displacement of the scapula, apart from that of the acromio-clavicular articulation, may depend upon different causes. In general, it is produced by a relaxation of the fibres of the broad dorsal muscle, as it passes over the inferior angle of this bone. So far as my observation extends, the affection is most common in young girls, of a feeble, delicate organization, about the age of puberty. It is also occasionally met with in boys, either from natural weakness, or from the violent, habitual exertion incident to certain avocations. When the affection exists in its worst form, the relaxation of the muscle may be so great as to permit the lower angle of the scapula to project in a very unseemly manner. In some instances both sides suffer simultaneously, and then the deformity is, of course, materially increased. Aching pain and weakness of the corresponding limb are ordinary concomitants of the complaint.

Occasionally the broad dorsal muscle, in consequence of a fall or blow, is forcibly wrenched from its connections with the scapula, and slips down beneath the inferior angle of the bone, which then forms a remarkable prominence immediately under the skin. The accident is easily recognized by the history of the case, by the contused condition of the soft parts, and by the loss of function in the superior extremity.

When the displacement is caused by a weak and relaxed condition of the dorsal muscle, the most reliable remedies are chalybeate tonics, friction with stimulating lotions, elec-

tricity, the cold shower-bath, and exercise in the open air.   The arm should be supported in a sling, close to the side of the body, and the inferior angle of the scapula kept in place by means of a suitable pad secured around the trunk, or, what is better, the plaster jacket.   In the traumatic form of the affection leeches and saturnine applications will be required, and the limb should be well raised and carried backwards, so as to afford complete relaxation to the injured muscle.   Reattachment of the torn fibres should be aimed at by keeping the scapula perfectly at rest for a long time, otherwise redisplacement will be inevitable.   This occurrence, however, is of less importance than is generally supposed, as in time the parts, in great measure, if not completely, regain their original power.

Serious malposition of the scapula sometimes arises from paralysis of the rhomboid muscles, chiefly in young, anemic persons, of a scrofulous habit of body.   Sedentary occupation and constrained posture powerfully predispose to its occurrence.   Great deformity is apt to attend, the posterior border and inferior angle of the scapula being widely separated from the trunk, and standing out in bold relief.   The treatment should consist of tonics and of various local means calculated to restore the functions of the affected muscles. Ammoniated lotions with the addition of strychnia, blisters, and the cold shower-bath, will be particularly serviceable.

DISLOCATIONS OF THE SPINE.

The vertebræ are so firmly connected to each other, and, excepting those of the neck, admit of such limited motion, that any injury directed against them is much more liable to break than to luxate them.   Even in the cervical region, where the mobility is much greater than anywhere else among these bones, the accident is exceedingly uncommon, and it is fortunate that it is so, since it is almost always fatal, owing to the violence in-

Fig. 646.   Fig. 647.

Dislocation of the Spine between the Fourth and Fifth
Cervical Vertebræ. The Cord was torn, the Paralysis being
complete, and Death occurred in a few days.

Dislocation of the Spine seen laterally.

flicted upon the spinal cord, as shown in figs. 646 and 647, causing death not unfrequently in an instant, or, at furthest, within the first few days.   When the patient survives the more immediate effects of the dislocation, he is very apt to perish from inflammation of the spinal cord and its envelops, at a period varying from a few weeks to several months. Hence, whether the accident be considered with reference to its primary or secondary effects, the prognosis must be equally guarded, few persons, under any circumstances, recovering.   In a dislocation of the sixth and seventh vertebræ, under the charge, many years ago, of Dr. Willard Parker and myself, death occurred in less than forty hours. The patient, a young circus-rider, met with the accident while engaged in tumbling in the ring; it was instantly followed by paralysis of all the extremities, and he gradually fell into a state of unconsciousness, which continued until he expired.   The neck was stiff and painful, but there was no sign of displacement.   On dissection, the articulating processes and bodies of the sixth and seventh cervical vertebræ were found to be completely detached from each other on the right side, but on the left the processes were still slightly adherent, while the connection between the bodies of the bones was perfect, although in a high state of tension.   The two contiguous spinous processes were completely severed. There was no fracture.   The spinal cord was sensibly compressed by the partial rotation

of the seventh vertebra, and there was a slight effusion of blood in the spinal canal at the seat of the injury.

In another case, that of a large, heavy man, twenty-six years of age, who was admitted into the Jefferson Medical College Hospital in 1879, under Dr. S. W. Gross, on account of dislocation of the fourth and fifth cervical vertebræ, attended with fracture of the contiguous bones, produced by a fall from the top of a railway car, the most prominent symptom was complete paralysis of all the extremities, with severe pain at the seat of the injury, priapism, and retention of urine. The respiration was unaffected. He survived the accident nearly two months and a half, suffering greatly from pain all the while, and becoming gradually more and more emaciated. The bowels acted naturally, but the urine, which had at first to be drawn off with a catheter, at length began to dribble away, and so continued up to the time of death. Hyperæsthesia in a high degree was also present during the last five or six weeks. A post-mortem inspection revealed the existence of a large clot of blood at the seat of the injury, compressing the spinal cord, and reducing it to nearly one half of its natural diameter. There was hardly any displacement of the luxated bones.

The above cases afford a good type of the effects which usually follow dislocations of the vertebræ. When the lesion occurs above the origin of the phrenic nerve, death is often instantaneous from stoppage of the respiration; if seated farther down, the patient may live for some time, and eventually even recover, although such a contingency is an extremely remote one. The diagnosis is generally very obscure, and it is usually impossible to determine whether the accident is a dislocation or a fracture, or a combination of both, while the treatment must, of necessity, be altogether empirical. The principal symptoms are paralysis of the extremities, tympanites, obstinate constipation, and retention of urine, which soon becomes loaded with phosphates, causing inflammation and ulceration of the bladder. If the patient survive any length of time, severe bedsores are liable to form upon the nates and other parts of the body, thus greatly increasing his suffering.

The most common cause of dislocation of the spine is external injury, as a blow, fall, or sudden wrench. An instance has been reported by La Salle in which the fifth and sixth cervical vertebræ were severed by a violent muscular effort, the patient, a maniac, dying in thirty-six hours. Occasionally the displacement is the result of ulceration of the vertebræ or the partial destruction of the ligaments.

As it respects the *reduction* of these dislocations, it is impossible to prescribe any regular or methodical course of procedure. Most practitioners, dreading interference on account of the danger of sudden compression of the spinal cord, and the consequent destruction of the patient, are in favor of letting the parts alone, hoping, with judicious management, for gradual recovery. Such a plan, it seems to me, is both wise and proper, at least in most cases, especially in those in which it is impossible to determine the diagnosis, or where the symptoms, although well marked, are not at all urgent, the patient having a tolerably good use of every part of the body save the one immediately concerned in the mischief. Under such circumstances, time and a "masterly inactivity" will often accomplish more than the most skilful interference. But there are exceptions to every rule, and while most cases of this kind should not be meddled with, I would strongly advise an opposite course where, the symptoms being well marked, and the danger urgent, there is reason to believe that the patient will, if not relieved, speedily perish. In such an event any attempt to save him, however desperate, would be perfectly justifiable and proper. If we succeed, we obtain a victory; if we fail, we can but hasten an occurrence otherwise inevitable. A number of instances are upon record in which the reduction was performed successfully. Thus, Dr. James R. Wood safely restored, by manipulation, a partial dislocation of the cervical vertebræ in a child; and Dr. Ayres, of Brooklyn, happily succeeded in a case of complete luxation of these bones ten days after the accident. The patient, a tall, muscular man, thirty years of age, had been violently struck on the back of the neck, the

Fig. 648.

Bilateral Dislocation of the Fifth Cervical Vertebra.

anterior portion of which was found to be remarkably convex from the blow, bulging forwards, and lifting up the larynx, as seen in fig. 648. The head, as the man sat in his chair, was thrown backwards and permanently fixed, the face being turned upwards. The posterior part of the neck exhibited a sharp, sudden angle at the junction of the fifth and sixth cervical vertebræ, around which the integument lay in folds. It was difficult to reach the bottom of this angle, even with strong pressure of the fingers, and, of course, the regular line formed by the projecting spinous processes was abruptly lost. The patient complained of intense pain at this part, and swallowed and breathed with difficulty; but there was not the slightest paralysis or diminution of sensation. The reduction was effected by means of the hands of the surgeon and of two assistants, applied to the chin and occiput in such a manner as to draw the head, at first, directly backwards, then upwards, and finally forwards, counterextension being made with two folded sheets stretched obliquely across the shoulders. The system was completely relaxed by chloroform, and the bones were distinctly felt slipping into their natural situation. No unpleasant symptoms followed, and at the end of a week the man had the complete use of his head and neck.

A traumatic luxation of the *occipito-atloid* articulation occasionally occurs, and generally, if not invariably, proves promptly fatal. The accident, until recently, was regarded by most writers as impossible, on account of the firm connections and restricted motions between the two bones.

A slow species of displacement occasionally occurs in this joint in children and youths, from scrofulous disease of the body and articular surfaces of the atlas, or of this bone and of some of the other vertebræ. Several examples of it have come under my personal observation, and the subject has been ably discussed by Schupke and other German writers. The severe local suffering which it produces is best allayed by rest and recumbency, leeches, blisters, and issues, especially those made with the actual cautery, while the constitution is to be improved by tonics and alterants, as quinine, iron, and the iodides. When all disease is arrested, the patient may exercise in the open air, the neck and head being well supported by appropriate apparatus.

The *atlo-axoid* articulation, enjoying a much wider range of motion than the preceding, is more liable to luxation by external violence, the most common causes being blows upon the back part of the head, forcible torsion of the neck, tumbling, and standing on the head, eventuating in rupture of the ligament of the odontoid process, and the projection of this process against the spinal cord, inducing fatal compression. Lifting children up by the occiput and chin, in play, may produce this accident, as in the memorable case related by J. L. Petit, of a little boy, who, being thus raised up in the air, struggled so violently as to dislocate his neck, dying on the spot. The nature of the lesion may be suspected when, by a sudden twist, blow, or wrench, the head is turned to one side, and cannot be restored to its natural position, the sterno-mastoid muscle being relaxed, and the part exquisitely painful. Unconsciousness usually succeeds the occurrence, and the patient, if not promptly relieved, soon expires. When the symptoms are urgent, an immediate attempt should be made to reduce the dislocation by inclining the head towards the side to which it is directed, in order to disengage the articular processes, a most hazardous step of the operation, and one which may instantly cause death by compression of the spinal cord. The processes being liberated, the head and neck are next brought to their natural position by rotating them gently in a direction contrary to that in which the luxation occurred.

Finally, there is occasionally a species of *subluxation* of the spine, consisting, as the name implies, in a partial displacement of the vertebræ, most frequently met with in the dorsal region. It may be caused by injury applied directly to the part, or, indirectly, through a fall upon the buttocks, in which these structures and the body are forcibly pushed towards each other, the violence of the shock being concentrated upon the ligaments, which, being thus forcibly rent asunder, leave a corresponding gap between the contiguous spinous processes. The accident is generally attended with severe concussion, and, occasionally, even with compression, of the spinal cord, thereby seriously endangering the patient's life. Sometimes there is partial paralysis, with retention of urine, and other unpleasant symptoms. The treatment is by recumbency upon a soft hair mattress, with the application of leeches and medicated lotions to the seat of the injury, and such internal remedies as the particular exigencies of the case may seem to demand.

DISLOCATIONS OF THE RIBS AND COSTAL CARTILAGES.

Dislocations of the costo-vertebral articulations from external injury must be extremely rare, if, indeed, they are not altogether impossible. That this is true, any one may satisfy himself by inspecting the mode in which the ribs are connected to the vertebræ; the ligaments are both numerous and powerful, and, besides, each joint is protected by a great thickness of muscles, so that these bones, instead of yielding at their junctions, will be much more apt to give way in their continuity. The possibility, however, of the accident was not only admitted, but strenuously maintained, by many of the older surgeons, especially by Paré, Barbette, Platner, and Heister, in whose works may even be found an account of what they regarded as varieties of the lesion. But modern experience is entirely opposed to such a conclusion; in truth, there are altogether not more, perhaps, than half-a-dozen well-authenticated cases of dislocation of the costo-vertebral articulations upon record, and in nearly every one of these the injury was associated with fracture of the ribs, or of the ribs and spine; all proved fatal, and in none was it possible to make a satisfactory diagnosis during life. Such an accident must, therefore, be entirely beyond the resources of surgical art; even if it were possible to detect the nature of the affection, still it would be impracticable to remedy it, except upon general principles, any direct interference being out of the question.

Dislocation of the ribs from their cartilages, and of the latter from each other and from the sternum, is also a rare occurrence, although not as much so as displacement of the costo-vertebral articulations. I have myself seen several cases of the kind, one of which I attended along with Dr. J. R. Pirtle, the patient being a man, sixty years old, who fell from a scaffold, a distance of ten feet, upon the stone steps below, his left shoulder and chest receiving the blow. Immediately after the accident there was violent dyspnœa, and the patient heard and felt, at every inspiration, something snap and jerk in his side, similar to the noise caused by pulling a finger-joint. Upon examination, this was found to proceed from a dislocation of the cartilages of the last three ribs from the sternum, the pieces playing to and fro during the movements of the chest. A fracture also existed in the left clavicle. In another instance the third and fourth ribs on the right side were severed from their cartilages. The remarkable case related by Sir Charles Bell, in his Surgical Observations, in which all the ribs were dislocated from their cartilages by the thorax being violently compressed between a wall and the beam of a mill, is familiar to every surgeon. Occasionally the costal cartilages are separated from each other.

Whatever form these costal dislocations may assume, their existence necessarily implies the infliction of severe injury, which cannot fail to tell badly upon the soft parts, both externally and within the chest, and to be followed, when not immediately fatal, by violent inflammation. Hence, besides the attention required by the local mischief, great care is demanded on account of the state of the system; in the first instance, to bring about reaction, and, secondly, to moderate the resulting excitement by appropriate antiphlogistics. The topical treatment is by bandage and compress, as in fracture of the ribs, the patient being compelled to breathe chiefly with the aid of the diaphragm.

DISLOCATIONS OF THE PELVIS.

Notwithstanding the great extent of the *sacro-iliac* surfaces, and the vast strength of the ligaments by which they are connected together, observation has demonstrated that they may occasionally be displaced along with the pubic symphysis, by external violence. Dr. Thomas Harris, of this city, met with a case of dislocation of these bones in a woman, thirty-five years of age, from a blow upon the sacrum inflicted by the husband's fist. In general, however, a much greater amount of force is necessary to produce such an accident, and hence there must almost always be more or less contusion of the soft parts, both externally and internally, extensive ecchymosis, concussion of the spinal cord, injury of the sacral nerves, and fracture of some of the pelvic bones, thus seriously, if not fatally, complicating the case. Even when the patient survives the immediate shock of the accident, he is very liable to perish from the subsequent inflammatory and suppurative irritation, perhaps weeks after the primary effects have passed off.

Violent kicks or blows, and compression of the body between two hard and resisting objects, as a wall and a carriage, are the usual causes of this dislocation. The displaced bone is thrown backwards and upwards, forming a distinct prominence beneath the skin, easily perceptible by sight and touch, and attended with marked crepitation. The limb of the affected side is shortened and powerless, the crest of the ilium is raised beyond the

natural level, the fold of the natis is flattened, the tuberosity of the ischium is higher than that on the sound side, and the ramus of the pubic bone lies somewhat posterior to the plane of its fellow. The parts are contused and exquisitely painful, and the patient is unable to lie upon his back, or to void his urine.

In the treatment of this luxation, the most important object, that, indeed, upon which the safety of the patient mainly depends, is to prevent the ill effects of inflammation, by the observance of perfect rest and the most rigid antiphlogistic course, of which leeching, anodyne fomentations, and blisters form most valuable constituents. When the inflammation has been measurably subdued, the parts should be covered with an ammoniac and mercurial plaster. The reduction, which is easily effected by pressure, is maintained by a compress and broad immovable bandage, secured, if necessary, by thigh and shoulder straps. Great attention must be paid to cleanliness, as defecation will be both painful and inconvenient; and the urine must be regularly drawn off with the catheter. In a case mentioned by Hoin, the articular surfaces refused to come together until after the patient had begun to walk about, when the weight of the limb drew them gradually in place.

The *pubic symphysis* is sometimes wrenched open by external violence, as I have witnessed in several cases in persons crushed between a railway car and the edge of the floor of the depot. The accident is generally fatal, not so much on account of the injury done to the joint and bones as of the violence sustained by the contents of the pelvic cavity. The treatment must be conducted upon the same principles as in dislocation of the sacro-iliac symphysis.

A separation of this joint occasionally occurs during utero-gestation, from softening of its fibro-cartilage, allowing the two bones to ride slightly upon each other, as in a case under my observation in a woman in her fifth pregnancy. The dislocation, beginning about a month before her confinement, was so great that she could not walk, or turn in bed, without severe suffering. The parts were exquisitely tender on pressure, and upwards of five weeks elapsed after parturition before they regained their healthy condition. Rest, recumbency, and leeches constitute the proper treatment, aided, when the patient is able to move about, by a belt with a pad upon the pubes.

The *coccyx* may be dislocated from the sacrum by external violence, as a fall, or kick, or by the pressure of the child's head in difficult parturition. The bone is usually thrown forwards or backwards. In a case reported by Dr. Roeser, it was displaced laterally, being torn away from the sacrum, and carried over towards the descending branch of the left ischium, where it formed a small but distinct tumor. The signs of the accident are, preternatural fixedness of the coccyx, with considerable shortening, difficulty in voiding the feces, tenesmus, and retention of urine. Reduction is effected by introducing the index and middle fingers of one hand into the rectum, while with the assistance of the fingers of the other, applied externally, the bone is pushed into its proper position. Rest, fomentations, and leeches will be required during the after-treatment. The bowels should not be moved for a number of days, and then only by means of saline cathartics and enemas, as all motion and straining would interfere with the reparative process and might even reproduce displacement.

2. SUPERIOR EXTREMITY.

DISLOCATIONS OF THE HAND.

Dislocations of the *thumb*, especially of its metacarpo-phalangeal joint, are, in many respects, so peculiar as to require separate consideration. Displacement of the phalanges backwards is by far the most common, the disposition of the articular surfaces, and the ligaments by which they are connected together, rendering luxation forwards or laterally extremely difficult.

In luxation of the metacarpo-phalangeal joint, the head of the first phalanx is thrown backwards, as in fig. 649, upon the dorsal surface of the metacarpal bone, generally by violence applied to the distal extremity or to the palmar surface of the thumb, while the joint is immoderately extended. The metacarpal bone being thus impelled by the weight of the body, and the proximal phalanx by the object struck, causes the ligaments to give way, and the articular extremities to glide past each other. It has been

Fig. 649.

Dislocation of the Thumb on the Dorsum of the Metacarpus.

asserted that, when there is inordinate relaxation of the ligaments, mere muscular action is capable of producing the displacement, but the possibility of such an occurrence, especially in its complete form, is very questionable.

The deformity which attends this luxation is so peculiar as to be characteristic. A large tumor, hard and circumscribed, and formed by the head of the first phalanx, exists upon the back of the joint, while another, equally hard, but not quite so distinct, is perceptible on the palmar aspect of the thumb, representing the distal extremity of the metacarpal bone ; the thumb is sensibly shortened, and can generally neither be bent nor extended, its last phalanx, however, being usually flexed in consequence of the excessive tension of the tendon of the long flexor muscle. In most cases the head of the first phalanx will be found to rest upon the posterior and inner part of the metacarpal bone, and not, as is commonly alleged, altogether upon its dorsal surface, a circumstance which gives the thumb an appearance as if it were rotated a good deal inwards. The shortening of the member often amounts fully to one inch, thus giving it a stumpy, characteristic aspect.

The ligaments in this luxation are extensively ruptured, particularly the anterior : the extensor tendons are pushed backwards, and strongly stretched ; and the external head of the short flexor muscle is torn in two, allowing the end of the metacarpal bone to pass completely through its fibres. The anterior ligament remains attached to the sesamoid bones and the first phalanx, the latter of which, as it is thrust backwards during the accident, carries both along with it, so as to deposit them, as it were, between its anterior surface and the contiguous surface of the metacarpal bone. In this way a partition is formed by these parts between the two bones, extending back some distance, and constituting, as Mr. Lawrie, by whom this arrangement has been so well described, justly remarks, a serious mechanical obstacle to replacement.

The means that were formerly employed to effect the reduction of this dislocation, were often so severe as to inflict the most dreadful injury, sometimes followed by extensive erysipelas and even mortification. Instances, in fact, were not wanting in which the thumb was pulled off during the violent and long-continued efforts at restoration. In many cases, again, the parts were obliged to be left in their unnatural situation. Desault, in order to accomplish his purpose, in difficult cases, suggested the idea of making an incision behind the extremity of the dislocated bone, and raising it out of its position by means of a suitable lever ; and Evans went so far as to propose its removal altogether by excision. Charles Bell, on the other hand, attempted to remedy the evil by the subcutaneous section of one of the lateral ligaments, an operation which has frequently been performed successfully both in this country and in Europe. Sir Astley Cooper advises, after a fair trial of the ordinary means, an abandonment of the case, under the idea that the patient will eventually have a useful thumb without reduction. I allude to these views simply because they serve to show the great difficulty which so often attends this dislocation, and the harsh expedients suggested for overcoming it.

The most common method of effecting replacement is that by extension and counterextension. This plan has always answered admirably in the few cases of the accident which I have had to treat. The extension should be made by means of the clove-hitch, represented in fig. 650, secured over a wet cloth, or piece of buckskin, to protect the soft parts, and the counterextension with a stout silk handkerchief, the fold resting in the palm of the hand, while the ends, crossed behind the wrist, and brought around the front of the forearm, are held by an assistant. In this way the two forces may be applied with

Fig. 650.
Clove-hitch Knot.

great effect, in a line with each other, and without the risk of unduly exciting the muscles concerned in the displacement. After they have been in operation for a short time, the thumb should be inclined inwards, in a semicircular direction, towards the ulnar margin of the hand, at the same time that the dislocated head is urged forwards and downwards by the surgeon's own thumb. Powerful extension may also be made by means of Charrière's forceps, fig. 651, and Dr. Levis's apparatus, the latter of which, delineated in fig. 652, is constructed upon the principle of the spatha, so much employed by the older surgeons for reducing dislocations of the shoulder. It consists of a flat, narrow piece of hard wood, ten inches in length, the proximal extremity

of which is perforated on each side for the passage of two strong tapes, two feet long. Properly applied, as shown in fig. 653, the apparatus acts with great efficiency, afford-

Fig. 651.

Charrière's Forceps.

ing a powerful leverage, perfectly unyielding, and in every respect superior to the clove-hitch.

The reduction is sometimes easily effected by abduction and rotation of the thumb, the extension being maintained in the usual manner. If the effort fail, trial should next be

Fig. 652.
Fig. 653.

Levis's Apparatus for reducing Dislocations of the Thumb and Fingers.

made of the excellent method of Professor Crosby, of New Hampshire, originally practised in 1826. It simply consists, as the adjoining cut, fig. 654, clearly exhibits, in pushing the phalanx back, until it stands perpendicularly on the metacarpal bone, when, by strong pressure directed against its base, from behind forwards, it is readily carried by flexion into its natural position. If this plan also fail, the only resource is the subcutaneous division of the tendon of the long flexor muscle, which is frequently, if not generally, the chief obstacle to replacement.

Fig. 654.

Crosby's Method of Reduction.

Fig. 655.

Forward Dislocation of the Thumb.

The annexed sketch, fig. 655, exhibits a plan of the dislocation of the head of the phalanx of the thumb forwards towards the palm of the hand. As already stated, it is an occurrence of great rarity. The symptoms are characteristic.

Dislocation of the *trapezio-metacarpal* joint may occur in four different directions, the end of the metacarpal bone being thrown off from the articular surface backwards, inwards, forwards, or outwards; the first two forms of the accident, however, are by far the most common, as will be apparent from an examination of the structure of the articulation and the arrangement of the muscles stretched along its anterior and outer surface.

Luxation *backwards* is always occasioned by external injury, as a blow or fall upon the dorsum of the thumb or the extremity of its metacarpal bone, by which the latter is sud-

denly and violently turned towards the palm. The signs of the accident are characteristic. A hard prominence is seen and felt upon the back of the trapezium, or at the posterior and radial surface of the hand, formed by the displaced head of the bone, the thumb is in a state of forced flexion, without the possibility of being extended, and the tendon of the extensor muscle is powerfully stretched, presenting itself as a firm, rigid cord behind the luxated bone. In order to effect reduction, two assistants are required; one to fix the hand by grasping the wrist, and another to pull the thumb with a clove-hitch. When the parts are thus drawn in opposite directions, the surgeon pushes the head of the bone forwards and downwards towards the palm, into its natural position. Sometimes the merest pressure from behind forwards and from above downwards is sufficient for the purpose. For some days the hand should be supported upon a broad splint, and means employed to moderate inflammation.

I have occasionally seen a partial dislocation of the metacarpal bone of the thumb backwards from inordinate relaxation of the ligaments. The occurrence is most common in weak, delicate women, and requires tonics, the cold douche, electricity, and a series of small blisters for its relief.

In the luxation *inwards*, which is exceedingly infrequent, the metacarpal bone of the thumb is wedged in between the trapezium and the head of the metacarpal bone of the index-finger, so as to extend the thumb, and cause the trapezium to form a projection at the outer and back part of the palm. In the reduction the extension and counterextension are conducted as in the preceding case, but they must be kept up a longer time, and, as the head of the bone approaches the trapezium, the thumb must be inclined towards the inner side of the hand, in order to relax the flexor muscles.

DISLOCATIONS OF THE FINGERS.

The phalangeal joints are susceptible of luxation backwards, fig. 656, an occurrence which can only be caused by severe force, and which is always so well characterized as

Fig. 656.

Dislocation of the Finger.

to render any description of the signs unnecessary. The reduction is effected by extension and counterextension, aided by pressure upon the head of the displaced bone. The accident is extremely rare. In a case under my charge of a compound dislocation of the last joint of the right middle finger, in a stout, healthy man, the injury was produced by a fall, in which the end of the finger was struck violently against the ground. The distal phalanx lay upon the posterior surface of the middle one, a large wound existing in front. The reduction was easily effected, and the parts being well approximated by suture and collodion-plaster, I indulged the hope of a good cure. Presently, however, severe inflammation set in, terminating in necrosis of the two bones, and I was obliged to amputate the finger immediately behind the joint.

In dislocation of the *metacarpo-phalangeal* joints, also a very uncommon accident, the phalanx is usually displaced backwards, its extremity resting upon the posterior surface of the metacarpal bone. Of the luxation forwards I have seen but one case, and that

Fig. 657.

Dislocation of the Finger at the Metacarpo-phalangeal Joint.

was of many years' standing; the finger was considerably shortened, and stood out in an extended position, flexion being impracticable. A rare example of luxation of all the fingers at the metacarpo-phalangeal articulation forwards has been reported by S. H. Serre, of Paris.

Dislocation backwards is generally caused by severe blows upon the back of the hand, or the extremity of the finger, while it is immoderately bent. The case is recognized by the existence of a hard tumor in the natural site of the knuckle of the hand, fig. 657, and by the shortened and flexed condition of the finger, the extension of which is impracticable.

The reduction is usually not difficult. To effect it, extension is made upon the finger by means of a suitable lac, fastened with a sailor's noose, and counterextension upon the hand, while firm and steady pressure is made by the surgeon's thumb upon the head of the displaced bone. When these efforts fail, recourse is had to Charrière's forceps or Levis's spatha, both of which may generally be used with admirable effect, as they are powerful means not only for securing a firm hold, but for controlling the movements of the finger during the necessary manipulations.

Excepting by the bursting of a gun, or other severe violence, dislocation of the *carpo-metacarpal* joints must be regarded as impossible, owing to the intimate manner in which the four last bones of the metacarpus are connected with each other, and with the bones of the second row of the carpus. Under such circumstances the injury is generally so great as to require amputation or excision, the latter operation always taking precedence when it is in our power to save any portion of the hand likely to be of service to the patient. Conservative surgery may do much in these cases to prevent mutilation by a careful use of the knife and pliers immediately after the occurrence of the accident, when the parts are tolerant of manipulation, and admit of being put in proper form for speedy reunion. A surgeon who cuts off a whole hand when the removal of a portion will suffice, has no just conceptions of his duty.

DISLOCATIONS OF THE CARPAL BONES.

From the firm connections and limited motions which characterize the carpal joints, it is evident that any displacement of them must be of very uncommon occurrence. Indeed, it was formerly asserted that such an accident was altogether impossible; a statement which has been contradicted by modern experience, which has not only established the fact, but elucidated the pathology and treatment of the lesion. The bones most liable to suffer in this way are the magnum, cuneiform, and pisiform, the occurrence being nearly always preceded by a relaxed condition of the ligaments, weakening their connections, and predisposing them to displacement under the application of comparatively slight force. The luxation is seldom complete. Maisonneuve has related a case in which the second row of carpal bones was dislocated posteriorly from the first row ; and a few examples of a similar kind exist in the annals of surgery.

Of the three bones above mentioned, the *magnum* is the most liable to dislocation : women are supposed to be more subject to it than men, owing to the greater mobility of the carpal joints, and the weaker state of the ligaments. The accident, which always occurs in a backward direction, is caused by forced flexion of the wrist, from falls, or other injuries, upon the back of the hand, wrenching the bone from its connections with the head of the corresponding metacarpal bone, and pushing it out behind, where it forms a hard, well-defined tumor, which increases when the wrist is bent, and diminishes when it is extended. Several cases have been observed in which the accident happened during the throes of parturition while the woman was forcibly grasping some substance with her hand; and in an instance related by Bransby B. Cooper, the person possessed the faculty of luxating this bone at pleasure. The displacement, although always incomplete, is apt to be followed by severe tumefaction, which often temporarily obscures the diagnosis.

The reduction is effected by firm pressure, either with a tourniquet or some other suitable contrivance, applied to the bone from behind forwards, or in a direction contrary to that of the displacement, the hand being at the time in an extended state, in order to insure greater relaxation of the soft parts, and to increase the opening from which the bone has been ejected. The operation must be conducted with great gentleness, and the surgeon must not be disappointed if he do not succeed in his first attempt. In case there is much inflammation, leeches and fomentations will probably be required. To maintain the reduction, the hand must be placed in a straight position, upon two binder's board splints, well padded, and long enough to extend from the middle of the forearm to the ends of the fingers. If the tendency to displacement is very strong, as it usually is, it may be necessary to apply a compress directly to the luxated bone, with a view to a more direct concentration of the pressure. The apparatus must be worn for a long time, as the ligaments are very slow in uniting, but after the first fortnight it should occasionally be taken off, for the purpose of moving the wrist-joint, to prevent ankylosis.

Of dislocations of the *semilunar* bone, complete and uncomplicated, only a few examples are upon record. In a case observed by Professor Chisholm, of Baltimore, the accident was caused by a fall from a height of twenty-five feet upon the hand. The bone formed a hard tumor immediately beneath the skin, just above the last fold of the palmar surface

of the wrist, on a line with the radius. The fingers were partially flexed, and could not be extended. A corresponding cavity existed on the back of the hand. As reduction was found to be impracticable, owing to the complete rotation of the bone, excision was performed, an operation rendered unusually difficult on account of the very tense condition of the numerous ligamentous connections. Notwithstanding this an excellent recovery followed.

A singular case of compound luxation of this bone has been reported by Mougeot. A carpenter, in a fall from a height of thirty feet, upon the palm of the hand, received a wound half an inch in length near the wrist-joint, attended with an escape of the semilunar bone, which, as it adhered only by a few ligamentous threads, was readily removed. The wound speedily healed, and the man recovered with a good use of the hand.

In a case of compound dislocation of this bone which I attended with Dr. M. O'Harra, the accident was caused by a fall from the platform of a railway car under motion, in which the patient, a stout young man, struck his hand upon a rock. A wound, half an inch in length, occupied the ulnar side of the wrist. Erysipelas and pyemia ensued, placing life for some time in imminent peril. As the case did not come under our charge until two days after the receipt of the injury, when the parts were excessively painful and swollen, no attempt could be made at reduction, and as the bone was attached only by a few shreds of ligamentous structure it was subsequently removed. Extensive suppuration occurred during the progress of the case, and the patient was a long time in regaining his health, with a tolerably fair use of his fingers. Bryant refers to a case in which both semilunar bones were dislocated simultaneously in a fall upon the hands.

Dislocation of the *cuneiform* bone is exceedingly uncommon; the accident can only occur when great force is applied, and must be treated upon the same general principles as the preceding.

The *pisiform* bone may be partially luxated by the action of the flexor muscle of the carpus, when its connections have been seriously weakened by disease of its ligaments. The occurrence is attended with some annoyance, and is difficult to remedy. When it is of sufficient importance to claim attention, the best plan is to place the hand in a slightly flexed position, in a wire case, extending from the middle of the forearm to the metacarpophalangeal joints, the carpal piece being so arranged as to form an obtuse angle with the other. A compress is applied to the lower and inner part of the wrist, in the situation of the displacement, and confined by adhesive strips and a bandage.

A case in which this bone was dislocated by an effort to lift a heavy weight, and drawn up the arm to a distance of nearly an inch by the flexor muscles of the carpus, is related by Mr. Erichsen. Similar instances are recorded by South, Fergusson, and other surgeons. When, after such an occurrence, restoration is impracticable, and the bone is in the way of usefulness, the best plan will be to excise it.

DISLOCATIONS OF THE WRIST.

A dislocation of the wrist-joint, as an independent traumatic lesion, is an exceedingly uncommon occurrence. Dupuytren, in the early part of the present century, after the dissection of a number of cases simulating this accident, positively asserted that he never saw an instance of it, except as a result of organic disease of this articulation. He assured himself that the pretended cases reported by various writers were simply examples of fracture of the inferior extremity of the radius, an accident which, as every one knows, is of very frequent occurrence, and is generally attended with symptoms closely resembling those of luxation of the wrist-joint. Observations, however, made since the time of the celebrated French surgeon, both in Europe and this country, indisputably prove that, although the lesion is exceedingly uncommon, its occurrence is not only possible, but that it has repeatedly been made the subject of clinical study. Luxation of the ulna alone, as a concomitant of fracture of the lower end of the radius, is sufficiently frequent.

The reason of the great infrequency of this accident is altogether of an anatomical character. From the manner in which the lower extremity of the radius is connected with the scaphoid, semilunar, and cuneiform bones, it is evident that any severe force applied to the hand, as in falls upon the palm or dorsum, must promptly be transmitted through the carpus to the radius rather than to the ulna, which can hardly be said to enter into the composition of the joint at all, except in so far as it affords some degree of lateral support. The consequence is that the radius, receiving the brunt of the injury, usually gives way at its inferior extremity, instead of allowing itself to be dislocated;

fracture of the brittle osseous matter being generally much easier than the laceration of the strong ligaments which naturally tie the contiguous surfaces together.

The carpal bones may be displaced from the radius and ulna backwards and forwards; lateral luxation cannot occur without fracture of one of the styloid processes, and then only in an incomplete manner.

In the luxation *backwards*, the carpal bones are driven up behind the ends of the two bones of the forearm, which lie in front of the muscles of the thenar and hypothenar eminences; the consequence is that there is great deformity of the wrist-joint, its antero-posterior diameter being much increased, although its breadth is nearly natural. The forearm is somewhat shortened, the hand and fingers are forcibly flexed, and the ulna is thrown considerably forwards and inwards beyond the line of the carpus. The radius and ulna retain their normal length, and the prominence on the back of the joint is characteristically hard, convex, and transversely elongated.

Fig. 658.

Dislocation of the Carpal Bones Forwards.

In the dislocation *forwards*, fig. 658, from Erichsen, the symptoms just described are reversed, the carpal bones lying in front, and the end of the radius and ulna behind. The hand and fingers are powerfully extended, the distance between the elbow and wrist is sensibly diminished, although the two bones retain their proper length, and the styloid processes can be distinctly felt behind at the lateral aspect of the hand, with the articular groove which naturally separates them, and which is now occupied by the tightly stretched extensor tendons.

These two dislocations are liable to be mistaken for fracture of the lower extremity of the radius and ulna, although such an accident could hardly happen in the hands of a scientific surgeon, perfectly vigilant, and bent upon the discharge of his duties. The principal points of distinction are, that, in luxation, there is much more of a tumor than in fracture, that the tendons of the hand and fingers are more evidently affected, being either violently extended or flexed, that the radius and ulna retain their normal length, and that the bones are, as it were, firmly interlocked with each other. In fracture of the radius, or of the radius and ulna, on the contrary, the deformity is less marked in the antero-posterior diameter, the two bones, if both are broken, are sensibly shortened, there is much more mobility, and, upon bringing the fragments in contact with each other, and then grasping the lower part of the forearm with one hand, while the patient's hand is moved with the other, crepitation may readily be elicited. Moreover, in luxation the styloid process of the ulna generally lies upon a plane somewhat anterior to that of the radius, whereas in fracture it is behind that bone.

The reduction of these two dislocations is sufficiently easy. All that is required is to extend the hand and counter-extend the forearm, immediately above its middle, while pressure is applied by means of the thumbs upon the carpal bones in a direction opposite to that of the displacement. The limb, enveloped in a roller, is supported upon a light splint, stretched along its palmar aspect, and kept constantly wet with some evaporating lotion. Ankylosis, so liable to occur after all injuries of this joint, is prevented by passive motion.

Congenital dislocations of the wrist have attracted much attention, chiefly through the labors of Dupuytren, Cruveilhier, Guerin, R. W. Smith, and Robert Adams, of Dublin, the latter of whom states that he saw within a few years, not less than thirteen examples of it. The carpal bones may be thrown forwards or backwards, forming, in either case, a well-marked, characteristic, angular prominence. The lesion is attended with atrophy of the bones, ligaments, and muscles; the hand is generally useless, and the fingers are variously deformed, being usually wasted and crooked. I lately saw a well-marked case of lateral displacement of the wrist in a puny female infant, three weeks old, the hand presenting towards the radius. The treatment must be conducted upon general principles, although it will seldom be of much avail.

DISLOCATIONS OF THE RADIO-ULNAR JOINTS.

1. The *inferior radio-ulnar* joint is liable to displacement in two directions, the ulna being thrown backwards in the one case, and forwards in the other, beyond the line of the

radius. The slightest anatomical inspection will serve to show, what experience has proved to be true, that the former luxation must be the more frequent of the two, although both are very rare as uncomplicated lesions. As an accompaniment of fracture of the lower extremity of the radius, displacement is by no means uncommon, especially the partial variety.

The dislocation *backwards* is usually the result of violence applied to the hand or forearm, during strong pronation, any sudden twist or wrench of the joint predisposing to its occurrence. The signs are characteristic. The hand is in a fixed state of pronation, and inclined a little towards its inner margin; the head of the ulna, directed obliquely across the radius, forms a distinct prominence above the level of the cuneiform bone; the fingers are slightly bent; the styloid process has lost its parallelism with the fifth metacarpal bone; and the inferior extremity of the forearm has an appearance of being unnaturally narrow, although, if some time has elapsed since the accident, this will probably be masked by the swelling. The reduction is effected by flexing the forearm at a right angle with the elbow, and then gradually but determinedly extending the hand, and rotating it outwards until it is brought into the supine position, when the bone will usually resume its natural relations.

The lower extremity of the ulna may be displaced *forwards* by a fall upon the wrist, by a violent wrench of the hand while in a state of supination, or by injury applied directly to the forearm. The accident is very uncommon. The symptoms are the reverse of those in the preceding dislocation; that is, the ulna, lying across the anterior part of the radius, forms a remarkable projection just above the carpus, while the forearm and fingers, slightly bent, are powerfully supinated, and cannot be brought out of this position without restoring the joint to its normal condition. The reduction is effected in the same manner as in the luxation backwards, the limb, as the bone yields, being gradually but forcibly pronated.

It will be necessary after both these luxations, as the ligaments will be slow in uniting, to keep the limb well bandaged, and supported by means of a padded splint, extending from near the elbow to the ends of the fingers. A firm compress is to be placed over the inner and forepart of the joint, the more thoroughly to protect it against a recurrence of the accident.

2. Dislocation of the *superior radio-ulnar* joint may occur in three different directions, the head of the radius being thrown from the sigmoid cavity of the ulna forwards, backwards, and outwards, the frequency of the accident being in the order here stated, although some authorities contend that the displacement backwards is the most common. This I have not found to be the case in my own practice.

The chief causes of dislocation *forwards*, fig. 659, are falls upon the palm of the hand, in which, the forearm being powerfully supinated, the head of the radius receives the whole force of the blow, and is thrown against the coronoid process of the ulna and the external condyle of the humerus. The accident, which is most common in young subjects, may also be produced by direct injury to the upper extremity of the bone, acting from behind forwards, as in the case of an elderly gentleman, recently under my observation, in which the luxation was caused by the kick of a horse which at the same time fractured the upper portion of the shaft of the ulna. Dr. Krackowizer, of New York, has recorded a case in which the displacement was occasioned, as was supposed, by violence inflicted in turning the child in delivery.

Fig. 659.

Dislocation of the Head of the Radius Forwards.

The signs of this accident are characteristic. There is an obvious vacuity at the upper and outer part of the limb, and the head of the radius can be distinctly felt in its new situation, in front of the elbow, rolling about under the finger, upon rotating the lower extremity of the bone. The forearm, slightly flexed, is either pronated, or in a state midway between pronation and supination, and every attempt to bring it into a straight line or to a right angle with the elbow is unsuccessful. When an effort is made to bend the limb suddenly, the head of the radius will be found to strike against the lower and fore part of the humerus, refusing to advance; a circumstance characteristic of the nature

of the accident. This dislocation is usually described as being accompanied by forced supination of the hand, but, in general, this is not the case.

The reduction is best accomplished by applying extension to the hand and counterextension to the middle of the arm, while the forearm, being semiflexed, in order to relax the two-headed flexor muscle, is forcibly supinated, at the same time that the head of the radius is pushed downwards and backwards, in the direction of its natural position. Replacement is often exceedingly difficult, and sometimes even impracticable; and, owing to the extensive laceration of the soft parts, there is a great tendency to a recurrence of the accident after the reduction has been effected, with imperfect recovery of the functions of the joint.

The most common cause of luxation *backwards*, fig. 660, is violence applied to the hand when the forearm is in a state of pronation, and carried beyond the natural line of the body. The accident is often associated with fracture of the condyle of the humerus.

The peculiar attitude of the limb in this luxation is almost characteristic of the nature of the injury. The forearm is semiflexed, and, together with the hand, in a fixed state of pronation; the fingers are also somewhat bent, and there is an evident void at the upper and outer part of the forearm, just below the elbow, while a short distance beyond this, over the external condyle, by the side of the

Fig. 660.
Dislocation of the Head of the Radius Backwards.

olecranon process, the prominence formed by the head of the displaced radius is distinctly perceptible, feeling hard and firm, and but faintly responding to any motions that may be impressed upon the lower extremity of the bone. Any attempt short of what is requisite to effect the reduction, to supinate the limb, to bring it into a straight line, or to flex it at a right angle with the arm, will be quite abortive, owing to the manner in which the radius hitches against the humerus.

Reduction is effected by making extension upon the hand and counterextension upon the lower part of the arm in the line of the displacement, while the head of the radius is pressed from behind forwards, towards the lesser tubercle of the humerus, at the same time that the hand and forearm are gradually but forcibly supinated. When the patient has not been relaxed by anæsthesia, the return of the bone is always indicated by a distinct snap.

A dislocation of the radius *outwards* is exceedingly uncommon. It occasionally exists, in an incomplete form, as a result chiefly of a relaxed condition of the annular ligament in persons of a feeble habit of body. Complete luxation in this direction can only occur when there is a rupture of the upper extremity of the interosseous ligament, and hence the lesion is apt to be complicated with fracture of the humerus or ulna, and severe injury of the soft parts. A fall upon the palm of the hand, propelling the radius upwards and outwards, with the whole force of the leverage of this bone, is the most common cause of the accident.

The symptoms are generally unequivocal. The head of the radius, resting upon the epicondyle of the humerus, forms a distinct prominence at the outer part of the elbow, easily recognized by the finger; the bone is situated higher up than natural, the distance between it and the olecranon being materially increased; the forearm is in a state midway between pronation and supination, the latter of which is impossible; and the movements of flexion and extension are, of course, much impeded. Besides these signs there is always a cord-like prominence along the front of the radius, as well as on the inside of the displaced head, formed by the tension of the external radial and long supinator muscles, which is gradually lost upon the outer and anterior surface of the limb. The reduction is effected by pushing the radius downwards and forwards, the forearm being bent at a right angle, and extension and counterextension made in the usual manner.

The reduction of these radio-ulnar dislocations is frequently attended with great difficulty; and as they are extremely liable to recur from the slightest causes, it is of great consequence, during the after treatment, to guard against the accident by the use of the compress and bandage, aided by a suitable apparatus, to insure perfect quietude, until the ligamentous structures are reunited. Passive motion must not be neglected, otherwise ankylosis may ensue.

The superior radio-ulnar joint is liable to a species of *subluxation*, similar to that of the

temporo-maxillary. I have seen a number of well-marked cases of it, in several of which it existed simultaneously on both sides; and in all it was manifestly dependent upon a relaxed condition of the annular ligament, allowing too great a latitude of motion between the head of the radius and the sigmoid cavity of the ulna. The subjects of this displacement are, for the most part, thin, weakly children of a strumous habit of body, and my experience is that females are more frequently affected than males. The movements of the joint are not materially impaired by the occurrence, unless it persists and gets worse, when the whole limb may become enfeebled by it. The cold douche, tincture of iodine, electricity, and a series of small blisters, with tonics to improve the general health, are the most suitable remedies.

Another form of dislocation liable to happen in this articulation is the *partial traumatic*, as it may be termed, chiefly met with in young children, from a sudden jerk, pull, or twist of the forearm, when the limb is in an overstretched state of pronation, the small size of the sigmoid cavity of the ulna at this period of life, and probably also a relaxed condition of the ligaments of the joint, favoring the occurrence. The accident is usually caused by the nurse in lifting the infant over the gutter, in dragging it rudely up to her side, or in her attempts to prevent it from falling. The head of the radius may be thrown either backwards or forwards, but the former displacement is by far the more common. The symptoms are generally well marked. A slight noise or snap is usually noticed at the moment of the accident; the child screams and is in great pain; the limb hangs motionless by the side; the forearm is slightly flexed, and the hand, strongly pronated, cannot be supinated without excessive suffering. There is ordinarily no swelling or deformity at the seat of the injury, not even after the lapse of several days.

The reduction, which occasionally occurs spontaneously during sleep, or during the manipulation necessary to detect the nature of the accident, is readily effected by extension and counterextension at the hand and lower part of the arm, while an effort is made to force the forearm into a state of supination.

DISLOCATIONS OF THE ELBOW.

The dislocations of the elbow-joint form a subject of very deep interest, not only on account of the frequency of their occurrence, but because of their great liability to serious complications and the consequent difficulty of their diagnosis and treatment. I am satisfied, from no little observation, that there are no luxations which are so little understood or so unscientifically managed. The principal reason of this is the want of correct knowledge of the structure of the elbow-joint, and of the complex arrangement of its osseous elements, with which few practitioners take the trouble to make themselves acquainted. The result is that cases of dislocation constantly occur which are mistaken for fracture, and which are, therefore, entirely neglected until it is too late to remedy them by means which, if timeously employed, would nearly always be sufficient to insure the reduction of the displaced bones, and the restoration of the bruised and lacerated tissues, with complete recovery of the functions of the articulation. It has been my lot to witness an unusually large number of such cases, generally at a period when nothing could be done for their relief.

The most common dislocation of the elbow is that in which both bones of the forearm are thrown upwards and backwards against the posterior surface of the humerus. Dis-

Fig. 661.
Dislocation of both Bones Backwards.

placement forwards is exceedingly infrequent, as it can only occur, with very rare exceptions, when the accident is complicated with fracture of the olecranon process, whereby the ulna is permitted to glide in front of the joint, which it must do with great difficulty when its superior extremity remains intact. Lateral luxation of both bones of the forearm from the condyles of the humerus is also very uncommon, and is necessarily incomplete, owing to the great extent of the articular surfaces in this direction, and the number, size, and strength of the muscles and ligaments surrounding the joint. Of the displacements of the superior radio-ulnar articulation a sufficient account has already been given. The ulna alone is sometimes luxated

upwards, the olecranon forsaking the sigmoid fossa of the humerus, and applying itself against the posterior surface of that bone.
1. Dislocation of both bones of the forearm *backwards*, fig. 661, or, more correctly speaking, backwards and upwards, usually occurs from falls in which the person, instinctively stretching out the arm to protect the body, receives the whole shock upon the palm of the hand. The two bones being thus impelled by the surface struck by the hand, and the humerus by the weight of the body coming in the opposite direction, the two forces explode at the elbow-joint, rupturing the ligaments, and driving the olecranon and head of the radius backwards and upwards. There can be no doubt that a contorted state of the forearm at the moment of the accident greatly promotes the luxation by increasing the strain. The accident sometimes occurs at a very early period of life, as in a case recently brought to my clinic, in a boy six years of age. Professor W. T. Briggs, of Nashville, met with it in a child only two years and a half old.

The signs of the dislocation are sufficiently obvious, presenting little variation in their character, unless the accident is conjoined with other injury. There is always great deformity at the elbow, and the forearm is generally in a partially flexed position. At the posterior part of the joint is the unnatural projection formed by the olecranon, and, in front, the still more conspicuous one formed by the condyles of the humerus, fig. 662, both usually perceptible by sight and touch, especially in lean subjects, and before the supervention of swelling. The forearm has generally a slightly twisted appearance, and occupies a position midway between pronation and supination, inclining, however, more to the latter than to the former; any attempt to flex or extend it is not only very

Fig. 662.

Dislocation of both Bones Backwards, showing the manner in which the muscles are put on the stretch.

painful, but in great measure impracticable. The fingers are somewhat bent, and the distance between the elbow and wrist is sensibly diminished, generally from an inch to an inch and a half, but only in front, for behind the limb retains its normal length. The muscles in front of the joint, especially the flexor and brachial, are stretched like tense cords over the condyles of the humerus, while the tendon of the three-headed extensor is carried away from the bone behind, and stands out in bold relief, forming one of the most conspicuous signs of the accident, as seen in fig. 662. Although generally the forearm is partially flexed and nearly immovable, occasionally it is almost straight, and can readily be bent and extended, not, however, without great pain.

Notwithstanding that the signs of this dislocation are usually characteristic, cases, nevertheless, occasionally occur in which the diagnosis is painfully obscured. Two circumstances principally contribute to render it so. One is the inordinate swelling which so generally follows the accident, and which is often present in a high degree before the surgeon has had an opportunity of examining the parts; the other, the existence of fracture of the bones composing the joint. When the humerus is broken off just above the condyles, the deformity closely simulates that produced by a dislocation backwards, the lower fragments, with the radius and ulna, being drawn in that direction, so as to give the back of the elbow a very prominent and distorted appearance, while the upper fragment will present itself quite conspicuously in front, under the flexor muscles. The points of distinction are that, in dislocation, the parts are fixed, and cannot be restored without a good deal of force, whereas, in fracture, they are easily moved and replaced, returning, however, to their unnatural situation the moment the efforts are discontinued. In dislocation, moreover, there is actual shortening of the anterior part of the forearm, but none in fracture; nor is there, in the former, any crepitation, which is so conspicuous in the latter. Fracture of the olecranon can always be distinguished by the elevation of the upper fragment, and the wide gap which separates it from the lower, and by the facility with which the surgeon can flex and extend the forearm. In fracture of the head of the radius there is no deformity of the posterior part of the elbow, and by grasping the bone with the thumb and finger above, as it is being rotated below, crepitation may easily be elicited, thus at once clearing up the diagnosis.

The reduction of this dislocation is extremely easy, if attended to immediately after its occurrence, but very difficult if it be neglected even for a short time. I have never been foiled in a recent case, but have met with many examples where every attempt

proved unavailing after the third week, and sometimes, indeed, even by the end of the second. I am not prepared to assign any reason for this; to say why a displacement that is always so easily rectified, if properly managed, in its earlier stages, should so soon become utterly irreducible, resisting and defying all the best directed efforts of the surgeon. It can hardly be supposed to be owing exclusively to inflammatory adhesions, for it is impossible that they could become either so extensive or so firm, in so short a time, as to produce such a result; but, whatever the true explanation may be, the fact remains, and the practical precept to be deduced from it is that all luxations of the elbow backwards should receive the earliest possible attention, their reducibility being in an inverse ratio to their duration.

But, although it is undoubtedly true that it is always extremely difficult, and sometimes utterly impossible, to reduce a dislocated elbow at the end even of two or three weeks after the occurrence of the accident, yet it would by no means be proper to abandon a case even if it were of three times that duration, inasmuch as a number of examples have been recorded which fully sanction such a course. I have myself met with several instances in which my efforts were rewarded, if not with complete success, certainly with very gratifying results, as it respected the functions of the joint, at the end of nearly two months. Sir Astley Cooper effected reduction at three months; Malgaigne, at three and a half; Blackman, Brainard, and Westmoreland, at five; Gerdy and Drake, at six. It is worthy of notice that the efforts, if long continued, may be followed by grave injury, as

Fig. 663.

Reduction with the Knee in the Bend of the Elbow.

violent inflammation, suppuration, and even gangrene. The brachial artery has been ruptured in more than one instance. Michoux, in an attempt to reduce a luxation of this joint, tore this vessel and the median nerve, and saved his patient only by immediate amputation of the arm. In a case treated by Velpeau, death was the consequence. Such examples teach a lesson which should not be lost upon the surgeon who is anxious to surmount obstacles at any and all hazard.

The reduction may be effected in various ways. The one that is usually adopted is to make a fulcrum of the knee in the bend of the arm, as in fig. 663, the patient being seated upon a chair, and the surgeon standing by his side in front, with his foot resting upon a high stool or upon another chair. Extension being made by grasping the lower portion of the forearm, the limb is gradually brought over the knee so as to disengage more effectually the ulna and radius from the condyles of the humerus. This manœuvre is usually very promptly successful. The efficiency of this method may be increased by steadying the shoulder with a sheet, the arm being passed through a hole in the middle.

A method which I have often successfully employed, especially in cases in which some time had elapsed, but which has not, so far as I know, been described by any one else, is to place the heel instead of the knee in the bend of the arm, the patient lying down, and the surgeon carrying his leg across the chest, while extension is made by pulling the hand and wrist. This procedure affords the operator an opportunity of exerting his strength to great advantage. As the bones yield, the forearm is bent towards the chest over the fulcrum, furnished by the foot, a step which materially promotes the reduction. The force of the extension may be much increased by securing a stout lac around the limb, immediately above the wrist, and throwing the noose over the neck and shoulder. Counterpressure may also be usefully made by an assistant placing his hands against the shoulder of the affected side.

A third method of reduction, based upon the same principles as the preceding, is to bend the limb forcibly round a bedpost, which is thus made to act as a fulcrum, while the requisite extension is made at the hand and wrist. This plan, however, although quite efficient, has the disadvantage of being both awkward and painful.

Finally, the reduction may often be readily effected by seating the patient upon a chair, and requesting two assistants to make extension and counterextension, one grasping the

wrist, the other the middle of the arm. The surgeon, standing behind the affected limb, then places his thumbs firmly upon the olecranon, and thus aids in pushing this process downwards and forwards into its natural position.

When unusual difficulty is anticipated, as when the patient is very muscular, or the luxation is several weeks old, the forearm may be carried forcibly backwards beyond the straight line, when, with very slight extension and counterextension, the parts will resume their natural relations. In a case in the hands of Dr. Waterman, of Boston, this method promptly succeeded after the failure of the more common procedures; and in one of my own, in a child six years old, a patient at the College Clinic, in which the dislocation was of five weeks' standing, I was equally fortunate, the reduction being effected in a few minutes. The coronoid process, in this method, being lifted out of the sigmoid fossa of the humerus, the muscles in front of the arm, by their tonic contraction, powerfully assist in drawing the bones of the forearm into their proper place.

When all these plans fail, the only resource is to employ the pulleys hooked to a noose fastened around the lower extremity of the forearm, and to a staple in the wall, floor, or bed. The counterextending band is secured around the middle of the arm, and is either confided to two stout assistants, or attached to some firm object behind the patient's head and shoulder. The patient should, of course, be recumbent, and fully anaesthetized. After the extending forces have been maintained for some time, the return of the bones will be promoted by steady pressure upon the olecranon. When these means fail, as will be extremely likely if the case is of longer standing than three weeks, it has been proposed to insert a narrow bistoury into the joint, so as to divide the resisting structures; but the operation, besides being dangerous, on account of the proximity of the brachial artery and nerves, has disappointed the expectations of its advocates.

Subcutaneous division of the tendon of the triceps has occasionally been practised with a view, as is alleged, of facilitating restoration of the joint. Professor Sayre, in 1871, reported two cases, respectively of fourteen and sixteen weeks, in which success seems to have followed such an operation. One of these cases was complicated with fracture of the coronoid process. Hamilton also succeeded in one instance in effecting, by this method, reposition in an old luxation. In a case of three months' duration in a girl eleven years of age, under my charge, in 1879, the operation signally failed, although I had previously divided the posterior and external lateral ligaments of the joint, and employed every possible justifiable means to accomplish my object. It is difficult on ana- tomical principles to conceive how such an operation could do any good, when it is remembered that the triceps in this accident is always relaxed by the posterior projection of the olecranon process.

Reduction being effected, the limb, carefully bandaged, is supported in a light wire case, and kept constantly wet with evaporating lotions. If the inflammation run high, as it generally does after such an injury, leeches and even venesection may become necessary. In every case, however simple, the greatest vigilance must be employed to prevent anky- losis. Passive motion must, of course, receive early attention.

In decidedly chronic cases of this accident, but where there is still a good deal of motion, the patient may often obtain a very fair use of the joint by breaking the olecranon process by forcible flexion of the limb. I have pursued this plan with excellent results in several instances, and equally encouraging effects have attended it in the hands of Crosby, Mus- sey, and other surgeons. In one case, I divided the bone subcutaneously, and, although a slight attack of erysipelas followed, good motion was obtained.

2. Dislocation of both bones of the forearm *forwards* is an extremely rare event, for- merly supposed to be impossible without previous fracture of the olecranon, or extensive laceration of the soft parts. Modern observation, however, has shown the fallacy of this opinion, by adducing a number of unequivocal cases in which the displacement existed as a pure, uncomplicated affection. At least ten such examples are upon record, including one recently observed by Dr. Forbes, of this city, and another reported by Dr. R. P. Hunt, of Chicago. Of eight cases of forward luxation of both bones of the forearm col- lected by Streubel, six were unaccompanied by fracture of the olecranon. The manner in which the occurrence may happen is not well understood; but, from some experiments performed upon the dead subject, it would seem that if, while the forearm is powerfully flexed upon the arm, severe violence be applied directly to the olecranon and head of the radius, the articular surfaces of these bones may be thrown forwards from the condyles of the humerus with much greater facility than would at first sight appear possible. The accident is most common in young subjects under fifteen years of age, and must neces-

sarily be attended with extensive rupture of the ligaments, if not also with severe contusion and laceration of the other soft parts.

The signs are sufficiently characteristic. When the ulna and radius are thrown completely forwards, in front of the condyles of the humerus, the forearm will necessarily be considerably shortened, whereas, when they retain their relation with the condyles, it will be elongated to the full extent of the length of the olecranon. The forearm, moreover, is slightly flexed, but by a little effort it may readily be extended, or even bent somewhat backwards. The skin and muscles in front of the joint are in a state of tension ; the end of the humerus can easily be felt posteriorly, where it forms a large prominence, and there is a well-marked depression, a kind of vertical gutter, in the natural situation of the olecranon, bounded on each side by the margins of the trochlea.

Two methods of reduction may be employed for this dislocation ; one consists in flexing the forearm at a right angle with the elbow, and making extension by pulling the hand and wrist, while the heel is applied as a fulcrum to the lower third of the arm, the patient being under the influence of anaesthesia. Or, instead of this, the extending and counterextending forces may be applied to the hand and shoulder, the limb being in a straight position, and pressure made upon the ulna and radius by means of the thumbs. During the after-treatment, leeches and fomentations will probably be required, with proper support of the limb, until the parts have united. Passive motion must be commenced at an early period.

3. *Lateral* dislocation of the elbow-joint, besides being extremely rare, can hardly occur in any other than an incomplete form, and as a consequence of severe injury extensively implicating the soft parts. The most common cause of the accident is a fall upon the wrist or hand when the forearm is in a flexed and contorted state ; and the displacement will be so much the more likely to happen if, the moment the extremity strikes the surface, the arm is forcibly impelled sidewardly. It may also be produced by violence acting directly upon the forearm and arm in opposite directions, as when the former is driven inwards and the latter outwards. In a case mentioned by J. L. Petit the accident was occasioned by the limb becoming entangled in the spokes of a wheel. The displacement may be inwards or outwards, and is often associated with partial dislocation backwards.

In the dislocation *inwards*, fig. 664, there is great deformity at the ulnar side of the elbow, produced by the olecranon and head of the radius, the latter hitching against the inner condyle, while the outer condyle presents an unusual prominence immediately beneath

Fig. 664.   Fig. 665.

Lateral Dislocation Inwards.   Lateral Dislocation Outwards.

the integument at the external aspect of the joint ; the forearm is partially bent, and somewhat supinated ; and the muscles of the arm, both in front and behind, are dragged inwards by the displaced bones.

In the luxation *outwards*, fig. 665, the ulna rests upon the external condyle, while the inner condyle forms a sharp prominence on the inside of the elbow; the forearm is slightly bent and rigidly pronated; the motions of flexion and extension are much impeded; and the flexor and extensor muscles are in a painful state of tension. Both in this and in the inward displacement there is a remarkable increase in the breadth of the articulation, along with considerable flattening of its anterior surface, and a twisted condition of the forearm.

These luxations are easily reduced by extension and counterextension, performed in the usual manner, and by coaptation by pressing the bones in a direction opposite to that of their displacement. In general, the object may easily be attained by simply bending the elbow over the knee, as in the dislocation backwards. The after-treatment requires great care, both to prevent redisplacement and ankylosis.

The only instance of complete lateral dislocation of the elbow with which I am acquainted is one recorded by Nélaton. It was observed in a man, sixty years of age, who was admitted for another disease, the accident

having taken place twenty years previously, from a fall from a height of thirty feet. The elbow was much deformed and ankylosed.

4. Dislocation of the *ulna* alone directly *backwards* is an uncommon accident, and can scarcely be complete without fracture of the coronoid process. The signs are usually characteristic. The forearm and hand are slightly flexed, and inclined inwards as if they were twisted on their axis; the olecranon forms a prominent projection at the back part of the joint, as in fig. 666; and the head of the radius, although usually somewhat displaced, may be distinctly felt in its natural situation during the movements of flexion and extension, both of which, but particularly the latter, are very much restricted and painful. The accident generally arises from a severe fall upon the inner and upper part of the hand, suddenly and forcibly impelling the ulna upwards and backwards, away from the head

Fig. 666.

Dislocation of the Ulna Backwards.

of the radius, the coronoid process lodging in the sigmoid cavity of the humerus. Its most prominent features are the contorted state of the limb and the remarkable projection of the olecranon, which will always serve to distinguish it from other lesions. When the coronoid process is broken off, the posterior deformity will be unusually great, and, although it may be effaced by extension, yet the moment the arm is left to itself it returns.

The reduction is generally easily effected by bending the arm over the knee, and extending the hand and wrist. Coaptation may be aided, if necessary, by pressure upon the olecranon with the thumbs. When the accident is attended with fracture of the coronoid process, special retentive means will be necessary, of which the best is a rectangular tin, felt, or gutta-percha case, the limb being properly bandaged, and a compress firmly bound over the olecranon.

5. Finally, the bones of the forearm are occasionally dislocated simultaneously in *opposite directions*, the ulna being thrown backwards behind the humerus, and the radius forwards upon a plane with the external condyle. The accident is uncommon, altogether not more than five or six cases having been reported. It is produced by falls from a considerable height upon the hand, impelling the two bones with great violence at a moment when the forearm is considerably flexed and forcibly twisted upon its axis. It is readily recognized by the singular form of the elbow, which is sensibly shortened transversely, but much increased in its antero-posterior diameter; by the great prominence at the back of the limb, formed by the olecranon process; and by the remarkable inward contortion of the forearm and hand, which are both slightly bent. On attempting to flex the limb, the head of the radius is found to hitch against the humerus, and to offer an insurmountable barrier to further progress. The reduction of the ulna is readily effected by placing the knee in the bend of the arm, and then pulling the hand and wrist; but that of the radius is more difficult, and will require, in addition, pressure upon the dislocated head outwards and backwards.

Dislocations of the elbow-joint are occasionally complicated with injuries of the humerus and of the bones of the forearm, the former generally manifesting themselves in fracture of one or both condyles or of the inferior portion of the shaft of the bone, and the latter in fracture of the olecranon process, or the upper extremity of the radius or of the shaft of the ulna. Fracture of the coronoid process is very uncommon and is difficult of diagnosis; but may be supposed to exist when there is inordinate tendency to displacement of the affected joint. Crepitation is either absent or indistinct. Such complications demand the same kind of treatment, after the reduction of the luxation, as when they constitute independent lesions.

Compound dislocations of this joint are serious accidents, liable to be followed by the worst results, both immediate and consecutive. Such is the extent of the articulating surfaces that any considerable exposure by wound is extremely liable to cause ulceration of the cartilages and caries or necrosis of the bones requiring their eventual removal, or, what is worse, the sacrifice of the limb. The danger is materially increased when there is fracture with displacement, the end of one of the bones perhaps protruding in the form of a sharp spicule at the wound. Such cases will seldom do well if an attempt be made to replace and save the parts in the usual manner. The patient, if young and vigorous, may, it is true, occasionally progress favorably, but the chances are that the limb will, by

and by, have to come off, or that life will be brought into imminent danger by the pro-tracted suppuration, ulceration, and hectic irritation. When, therefore, the symptoms are at all unpromising—the joint being extensively opened, the muscles torn, and the bones seriously involved—the best plan, as a rule, is to amputate immediately, the moment reaction has occurred ; or, under more auspicious, but still trying, circumstances, to ex-cise the ends of the injured bones, placing them afterwards in such a position as to insure their speedy reunion, and, at the same time, in as good a one as possible for the future usefulness of the limb.

Congenital dislocation of the elbow is uncommon, and occurs only in a partial form. Most generally the displacement is limited to the head of the radius, which, forsaking the sigmoid cavity of the ulna, applies itself against the outer condyle. The movements of the elbow and forearm are restricted, but not annihilated ; and, as the head of the luxated bone always becomes remarkably elongated as the patient advances in years, reduction is only practicable in infancy and early childhood.

DISLOCATIONS OF THE SHOULDER.

Dislocations of the shoulder-joint are of very common occurrence, being, as stated else-where, more frequent than all the other dislocations together, a circumstance which is easily accounted for by the shallow condition of the glenoid cavity of the scapula, and by the extraordinary latitude of motion peculiar to this articulation. Moreover, there is in many persons, females and children especially, a remarkable tendency to relaxation of the ligaments and muscles of the shoulder-joint, which thus powerfully predisposes to luxation, the slightest accident being, when the parts are in this condition, often sufficient to produce it.

Experience has shown that dislocations of the shoulder are not nearly as frequent in women as in men ; for the reason simply that they are much less exposed than the other sex to the various exciting causes of these lesions.

Age exerts a material influence upon the production of these dislocations. The sta-tistics of Malgaigne and others prove that children under fifteen years rarely suffer from them. I have myself not witnessed such an accident before the age of twelve ; but Pro-fessor Ashhurst and Dr. John H. Packard, of this city, have each met with one in a child under three years, and Mr. Flower, of London, refers to one in an infant only fourteen days old, caused by a violent wrench of the arm. From fifteen to twenty-five the accident is also comparatively rare, but from this period on it becomes more common, and from forty to sixty it reaches its maximum. After sixty there is a marked decline in its fre-quency, and few cases are met with after seventy.

The nomenclature of these luxations has been much encumbered by distinctions and refinements, which, so far from simplifying the subject, only serve to embarrass it. There are, in fact, only four principal dislocations of the shoulder ; all the rest, concern-ing which so much has been written, are mere varieties, hardly entitled to separate consideration, as they differ merely in the degree of the displacement. These dislocations are the axillary, subcoracoid, thoracic, and subspinous. In the first, the head of the hu-merus, as the name implies, is situated in the axilla, under the glenoid cavity of the scap-ula ; in the second, a little below and to the inner side of the coracoid process ; in the third, beneath the clavicle, on the anterior and lateral aspect of the chest ; and in the fourth, on the posterior surface of the scapula, either immediately below the acromion process, or on the dorsum of that bone below its spine. The first two of these luxations are by far the most frequent ; the other two are, in fact, so uncommon that they may properly be classed among the rare luxations. Especially is this true of the subspinous variety, of which hardly a score of cases are upon record. To show its infrequency, I may state that of 105 cases of dislocations of the shoulder, analyzed by MacCormac, of London, only one was of the latter description. To these more common dislocations may be added, as so many varieties of displacements, those cases in which the head of the hu-merus has been found in the subscapular fossa, and above the coracoid process, as in a case observed by Malgaigne. The nomenclature here suggested, besides indicating the situation of the luxated bone, is in strict conformity with that of the dislocations of the hip-joint.

Not a little diversity of opinion has been expressed respecting the relative frequency of the axillary and subcoracoid luxations. I have myself always regarded the former as the more common ; but by Malgaigne and Flower the preponderance has been ascribed to the latter, and a number of recent writers have adopted this view. Flower basis his conclu-sions upon an examination of forty-one specimens in the different museums of London, of

which thirty-one are said to be unquestionably of the subcoracoid variety. He also states that at the time he published the results of his observations, he was cognizant of fifty recent cases of shoulder dislocations, of which forty-four were of this nature. If the diagnosis between these injuries during life could always be satisfactorily determined, one might feel inclined to adopt this view, but this, as is well known, is frequently impossible. Fortunately the matter is of little, if any, real practical value one way or another.

1. The *axillary dislocation*, a very common form of the accident, also known as the subglenoid luxation, is usually occasioned by violence applied to the elbow or hand, the limb at the time being elevated, and widely removed from the body. It may also be produced, when the arm is in this position, by a fall or blow upon the shoulder, acting directly upon the head of the humerus. I have met with five cases in which the accident was caused by muscular contraction. In four of the cases the luxation occurred in an attack of epilepsy, and in the other simply from raising the arm inadvertently above the level of the head. Dr. Garrison, of Illinois, met with an instance in which it was produced in a fit of sneezing. However induced, the head of the humerus will be found to be in the axilla, immediately beneath the glenoid cavity, lying upon the inferior border of the scapula, as in fig. 667, between the subscapular muscle and the long head of the triceps. The axillary vessels and nerves are somewhat compressed, the capsular ligament is largely opened below, and the articular muscles are nearly always more or less lacerated, if not partially separated from their attachments. The supraspinate and deltoid muscles, particularly the former, are violently stretched and spasmodically

Fig. 667.

Axillary Dislocation.

contracted; the broad dorsal and great pectoral, on the contrary, are usually somewhat relaxed.

The *symptoms* are, inordinate prominence of the acromion, as exhibited in fig. 668, which is much more sharp and distinct than natural, with a well-marked depression just below this process; flattening of the shoulder, and unusual fulness of the axilla, caused by the presence of the displaced bone, which, on motion of the limb, can easily be felt rolling about between the thumb and fingers, especially in lean subjects. The height of the axilla is at least an inch to an inch and a half greater than on the sound side. The elbow projects considerably from the trunk in consequence of the tension of the deltoid muscle, the forearm is slightly bent, the arm is perceptibly lengthened, the fingers are benumbed from compression of the axillary nerves, and the whole extremity, stiff and powerless, is generally somewhat supinated, although not necessarily so, as I have repeatedly seen it inclined in the opposite direction. Flexion of the forearm, also, is not an invariable occurrence; generally it is said to be so, but a number of cases have come under my observation in which the patient was able to extend and bend it at pleasure. When the biceps and triceps are put considerably upon the stretch, as when the head of the bone is thrown unusually far inwards, the limb often presents a singularly twisted appearance.

Although the signs of this dislo-

Fig. 668.

Axillary Dislocation.

cation are generally well marked, there are few accidents which are so liable to be mistaken, and no pains should, therefore, be spared to establish a correct diagnosis. The most reliable phenomena are, the flattening of the deltoid muscle, the prominence of the acromion process, the fulness and increased height of the axilla, and the peculiar projection of the elbow, which cannot be brought in contact with the side without strongly inclining the body outwards. The latter occurrence may be regarded as especially valuable, as there is no other lesion that simulates it. Another sign, first pointed out by Professor Dugas, of Georgia, is the inability which the patient experiences in touching the sound shoulder with the hand of the injured limb while the elbow rests in front of the chest.

2. In the *subcoracoid* dislocation, originally described by Malgaigne, the head of the humerus, instead of lying below the glenoid cavity of the scapula, rests in the armpit, immediately below and a little to the inner side of the coracoid process, as in fig. 669, under cover of the coraco-brachial and pectoral muscles. The symptoms which attend this form of displacement are very similar to those which characterize the axillary luxation; but the head of the humerus is not so distinctly outlined, and cannot always, especially in very muscular subjects, be readily perceived, unless the elbow is considerably elevated and rotated upon its axis. The arm is usually a little longer than naturally, but occasionally it is actually shorter. The motions of the joint are much impeded, and the hand cannot be placed upon the sound shoulder, while the elbow is held at the antero-lateral aspect of the chest. The hollow in the axilla is less than in the axillary displacement, and there is less compression of the brachial plexus of nerves. The limb is more or less twisted upon its axis, and the forearm is partially flexed.

Fig. 669.   Fig. 670.

Subcoracoid Dislocation.   Thoracic Dislocation.

3. The *thoracic dislocation*, the subclavicular of the French surgeons, is comparatively rare, and is by some surgeons regarded simply as an exaggerated variety of the subcoracoid luxation. It is usually caused by violence applied directly to the head of the humerus, or to the elbow, when the arm is elevated, and carried behind the central line of the body. The bone is thrust to the sternal side of the coracoid process, immediately below the clavicle, resting against the second and third ribs, under cover of the pectoral muscles, as exhibited in fig. 670. The anterior and inner parts of the capsular ligament are extensively ruptured, and there is usually considerable injury sustained by the adjoining muscles, especially the subscapular, the infraspinate, and the small teres, which are often severed from their attachments. In a case described by Malgaigne, the head of the bone lay immediately beneath the integument, in the interval between the deltoid and pectoral muscles.

The acromion process in this dislocation juts out with great distinctness, the depression beneath it being much more conspicuous than in the axillary variety of the accident, from the manner in which the deltoid muscle is drawn over towards the chest; and the head of the humerus is generally easily detected just below the clavicle, forming a hard prominence which readily obeys the movements of the limb. The elbow stands off widely from the body, in a backward direction, and the arm is commonly shortened from half an inch to an inch. The pain is less severe than in the dislocation downwards, as there is no compression of the axillary plexus, but the impairment of the functions of the joint are greater.

The most important diagnostic marks are, the peculiar attitude of the limb, the extraordinary prominence of the acromion, and the position of the head of the bone just below the clavicle, where it can generally be both seen and felt.

4. The *subspinous* dislocation, fig. 671, is so uncommon that it is very properly considered as one of the rare forms of injury of the shoulder-joint. It is generally produced by a fall upon the elbow or hand, the limb being at the moment raised, and stretched out in advance of the body, a movement which has the effect of depressing the head of the humerus, and of throwing it backwards upon the posterior surface of the scapula. The posterior superior part of the capsular ligament is extensively opened, and the articular muscles are not only stretched, but often severely lacerated, the subscapular being generally detached from the lesser tuberosity of the humerus. The head of the bone usually rests immediately beneath the posterior angle of the acromion, upon the back of the neck of the scapula, or upon the posterior border of the glenoid cavity. In rare cases only does it lie upon the dorsum of the scapula below the spine, as the term subspinous implies.

The *symptoms* are usually well marked. The rotundity of the shoulder is diminished, but not completely effaced, the acromion is abnormally distinct, and the head of the humerus may be both seen and felt in its new position, at the posterior part of the shoulder, below the spine of the scapula. The arm is considerably shorter

Fig. 671.

Subspinous Dislocation.

than natural, and the forearm, strongly rotated inwards, is bent obliquely across the chest. The axilla is deprived of its fulness, and, upon making firm pressure there, before there is any considerable swelling, the finger can be made to sink into the glenoid cavity. The arm cannot be supinated, and all attempts to move it are productive of severe pain, owing to the manner in which the head of the humerus is impacted in its new position.

General Diagnosis.—Although the diagnosis of dislocations of the shoulder-joint is usually sufficiently clear, cases occasionally occur in which quite the reverse is true. There are several accidents with which they are liable to be confounded, and from which it is of great importance they should be correctly distinguished. Thus, mere contusion of the deltoid muscle, or a sprain of the articulation, sometimes simulates to a very perplexing extent the symptoms of luxation, by causing more or less obliquity of position of the arm, with inability to raise it; hence the case is liable to be treated with improper severity, violent extension and counterextension being perhaps employed, when nothing but the most simple means are necessary. In general, however, the diagnosis is usually easily determined by a careful inspection of the affected joint. When there is no displacement, the head of the bone will, of course, be found to occupy its natural position, the shoulder retaining its rotundity, and the arm its natural length. Motion, too, will be found to be perfect if the patient be examined under the influence of anaesthesia.

Great perplexity will be likely to arise when there is a fracture of the acromion, the neck of the scapula, or of the superior extremity of the humerus; hence, whenever such an occurrence is suspected, the surgeon cannot possibly be too much upon the alert. In each of these accidents there are three circumstances which, if carefully considered, will always serve to prevent mistake. These are, preternatural mobility of the parts, crepitation, and facility of reduction, followed by an immediate recurrence of all the symptoms the moment the surgeon relinquishes his hold upon the limb. In dislocation, the head of the humerus is firmly fixed in its new situation, and is, consequently, moved with difficulty; there is complete absence of crepitation, or, if there be any noise, it is very faint, and entirely different from that which is caused by rubbing together the ends of a fracture; and, lastly, the restoration of the displaced bone can be effected only after much effort, generally, indeed, not without energetic extension and counterextension. Moreover, the reduction being once effected, the articular surfaces usually retain their natural relations, having no disposition again to separate.

In fracture of the acromion, the outer extremity of the bone is drawn down by the weight of the limb and by the action of the deltoid muscle, giving the shoulder a sunken appearance, and the arm is sensibly elongated and supported by the patient's hand. Restoration is readily effected by raising the elbow, but, upon abandoning it, there is an immediate reproduction of all the former symptoms, thus at once deciding the nature of the injury.

In fracture of the neck of the scapula, a very rare accident, the acromion retains its natural position, but is uncommonly prominent; the arm is elongated, and crepitation is easily elicited by raising the elbow, which will also have the effect of restoring the form of the joint.

The signs of fracture of the head and neck of the humerus are generally characteristic. The extremity of the bone, constituting the upper fragment, retains its natural position, while the rough, angular end of the shaft projects upwards and inwards into the axilla, being drawn thither by the pectoral and dorsal muscles. There is no displacement of the acromion, the shoulder is less flattened than in luxation, and the arm, instead of being elongated or of the natural length, is materially shortened.

Treatment.— Various methods may be employed for effecting the reduction of these different forms of dislocation; but the best of all, especially in the axillary, is to place a fulcrum in the armpit, upon the luxated bone, while extension is made upon the forearm, just above the wrist. The most efficient fulcrum for this purpose is the heel of the surgeon, divested of its boot, he and the patient lying in opposite directions upon a bed or

Fig. 672.

Reduction with the Heel in the Axilla.

table; and the efficiency of the operation will be materially increased, if, after the extension has been maintained for a little while, the limb is gradually brought forwards over the body, so as to raise the bone upwards and outwards to a level with the glenoid cavity. I sometimes find that I can reduce the dislocation more promptly and with less effort by sitting between the patient's limbs, with my own leg carried obliquely over the trunk, as this affords a much more powerful leverage than in the ordinary procedure. When unusual resistance is encountered, the extension should be aided by means of a stout fillet, secured around the lower part of the arm by the clove-hitch, and thrown across the surgeon's neck and shoulder, as seen in fig. 672.

Fig. 673.

Reduction with the Knee in the Axilla.

Dr. Garms, instead of placing the patient upon his back, makes him lie upon the abdomen. The two towels are fastened around the arm, one just above the elbow, the other a short distance below the shoulder. The latter is then given in charge of an assistant, standing on the affected side, to draw the arm laterally, while the operator, sitting on the floor, seizes the former, and, employing the heel in the usual manner, makes extension downwards and backwards. The operation is particularly applicable to the axillary form of the accident, and is so simple as not to require the aid of an anæsthetic.

Dr. Samuel Logan, of New Orleans, practises a method of reducing this dislocation, in which the surgeon, placing his legs nearly at a right angle with the patient's body, with a slight inclination upwards, plants the heel of one foot in the axilla, against the ribs, so

as to press a little crosswise, while the base of the great toe of the other foot rests against the acromion process. The trunk and shoulder being thus firmly steadied, the necessary traction is made upon the forearm, as in the ordinary method.

Occasionally the reduction is readily accomplished by making a fulcrum of the knee, as in fig. 673, the patient sitting up, and the surgeon supporting his foot upon the edge of his chair, or upon a stool. The operation is particularly applicable to dislocations in delicate females, and in old, emaciated subjects. It is performed by inserting the knee as high as possible in the axilla, and then, the top of the shoulder being thoroughly steadied with the hand, carrying the elbow forcibly downwards and inwards towards the side of the body. This procedure is characterized by great simplicity, but lacks the efficiency of that in which the heel is planted in the axilla.

A very simple method of reducing this dislocation, represented in fig. 674, was practised by Brunus in the thirteenth century, and by White, Mothe, Bell, Thompson, and others in the last. Revived by Rust, Kluge, Firz, and Malgaigne, it has been known to

Fig. 674.

Reduction by the Perpendicular Method.

succeed when other expedients have failed. In the original plan the patient lies upon his back, while the surgeon, standing behind him, raises the limb perpendicularly above the head, the shoulder being firmly fixed with one hand upon the acromion process, and the requisite extension made with the other, by grasping the arm above the elbow. The efficiency of this method will be greatly increased if, as suggested by Mr. George Lowe, the patient be placed in the sitting posture against a couch, sofa, or bedstead, the scapula steadied with the foot, the extension made at the wrist, and the humerus rotated upon its axis as the head of the bone approaches the glenoid cavity.

Mr. Kirby, of Dublin, was in the habit of reducing this luxation by a method somewhat more complicated than any of the preceding, but not less efficient. The patient being seated upon the floor, a stout fillet was secured around the lower part of the arm, and confided to an assistant, while another assistant, also seated upon the floor upon the opposite side, steadied the scapula by encircling the chest with his arms, his fingers being interlocked in the axilla. When these preliminaries were arranged, the assistants carried each one leg behind and the other in front of the patient, so as to rest the soles against each other. The limb being now elevated nearly to a right angle with the body, the extension was made in a slow and gradual manner, while the head of the bone was urged upwards towards the glenoid cavity, the elbow being at the same time raised and brought towards the side.

I have never had occasion to employ the pulleys in recent dislocations of the shoulder, and can hardly imagine that they could be necessary even in very stout, muscular subjects, as any surgeon may with a little patience and skill effect reduction by the methods now pointed out, with the aid of anæsthesia. If a resort to the pulleys, however, be demanded, they must be employed with great care, lest harm should befall the axillary vessels ; for the very fact that restoration cannot be accomplished by manual effort is an evidence of probable complication, and should be sufficient at least to put the surgeon on the alert. The operation is performed during the recumbency of the patient, or as he sits on his chair, as seen in fig. 675. The shoulder is firmly fixed by means of a long fold of muslin, the arm

Fig. 675.

Extension with the Pulleys.

being passed through a hole in the centre, and its ends held by assistants, or fastened to a staple in the wall. The extending band is tied around the lower part of the arm just above the elbow, and secured to the pulleys, which are then put in motion, the forces being applied transversely, and the head of the bone, as it approaches its socket, being lifted up by the hands in the axilla.

The reduction in the thoracic variety is easily effected by placing the heel in the axilla, so as to fix the scapula, and making the extension obliquely downwards and a little backwards, in the line of the displacement. The patient should lie upon the sound side, and as the head of the bone approaches the glenoid cavity it should be urged on by the pressure of the foot, at the same time that the arm is brought over to the body, very much as in the dislocation downwards. The chief impediments to the reduction are the two spinate muscles along with the deltoid.

The reduction of the subspinous dislocation is effected by making extension and counterextension in the usual way, and urging the head of the bone from behind forwards by

Fig. 676.

N. R. Smith's Method of Reducing Dislocations of the Shoulder-joint.

means of the hand, until it can be perceived in the axilla, when the restoration is completed by bringing the arm gently downwards and backwards, first into a line with the body, and then a little in advance of it. The principal obstacles to the replacement are the supraspinate, subscapular, large teres, and great pectoral muscles, which are generally powerfully stretched.

Professor N. R. Smith, of Baltimore, in 1831, recommended a very effective method for reducing dislocations of the shoulder-joint, which has often been successfully employed by other practitioners, especially by his old pupils. It simply consists in making the counterextension, as seen in fig. 676, from the opposite wrist. In this way the scapula is very firmly steadied, when all that is required is to depress the limb of the injured side and rotate it slightly upon its axis, the knee being pressed at the same time against the head of the humerus in the axilla.

Reduction by Manipulation.—The different forms of dislocation now described may all be reduced by mere manipulation, especially in recent cases, although I believe that the heel in the axilla is generally preferable to every other. In many instances simple torsion of the limb, particularly by rotation from without inwards, is quite sufficient for the purpose. The operation is performed by grasping the lower part of the forearm, and then turning the limb upon its axis, which has the effect of throwing the head of the humerus backwards and outwards, towards the glenoid cavity, when all that is necessary to induce it to slip into its proper position is to bring the limb on a line with the trunk. In this manner, I reduced in a few seconds, in 1869, after the failure of other means, an axillary dislocation of nearly three months' standing. Restoration is sometimes readily effected by simply lifting the limb obliquely across the chest, the scapula being well fixed at the moment.

Manipulation, as practised by Professor Henry H. Smith, of this city, consists, first, in elevating the arm and flexing the forearm; secondly, in rotating the head of the humerus upwards, outwards, and backwards, as far as possible, by using the forearm as a lever; and, lastly, in rotating the head of the bone strongly upwards and inwards by a reverse movement, while the elbow is brought to the side, the palm of the hand looking down, instead of up, as in the second stage of the proceeding.

When the head of the bone is thrown forwards upon the chest, it must, as a preliminary step, be forced down into the axilla, by carrying the elbow as far back as possible, and then elevating it, when, rotation being properly executed, it will readily slip into the glenoid cavity. In the posterior luxation, the same object is attained simply by raising the arm and carrying it strongly forwards.

The method of reducing dislocations of this joint by manipulation was warmly advocated, and rules laid down for its performance, by Sir Philip Crampton, as early as 1833, in a series of papers on the subject in the Dublin Medical Journal. In the luxation downwards he made gentle extension at the wrist, to secure a long lever, and then slowly raised the limb to nearly a horizontal position, so as to relax the flexor and extensor muscles. He then suddenly pushed the arm upwards and a little forwards, towards the patient's face, or, in other words, rotated it inwards with the hand turned prone, and at the same instant forced the trunk suddenly backwards with the left hand placed below the axilla.

In the luxation forwards, "the surgeon," says Crampton, "should place his left arm, extended horizontally, immediately below the walls of the axilla, between the dislocated arm and the chest, and then, grasping the wrist in his right hand, he should draw the arm forcibly across the patient's body."

In recent cases mere pressure with the fingers, as originally practised by Avicenna, afterwards by Desault, and lately again by Richet and Pitha, is often sufficient to effect the object even without the aid of an anæsthetic, particularly in the axillary variety of the accident. The patient being seated upon a chair, the surgeon, standing at his side, places one hand upon the acromion process of the scapula, and the other, with the fingers semiflexed, in the armpit upon the head of the humerus, while an assistant gently raises the affected arm, or the surgeon does this himself by letting the elbow rest upon his forearm. By pressure, steadily and persistently directed, the bone is gradually lifted over the rim of the glenoid cavity, its return being frequently accompanied by a distinct snap. The object will be greatly facilitated if the muscles of the arm and shoulder are perfectly relaxed, and if, as the head of the humerus approaches the glenoid cavity, the arm be slightly rotated upon its axis.

In the method recently suggested by Dr. Kuhn, of Elbeuf, the force is applied to the scapula while the humerus is the fixed point. A conical-shaped cushion being placed in the axilla with the apex directed upwards, the surgeon, standing at the patient's side, slightly lowers the arm, and presses it firmly against the cushion, so as to convert it into a lever of the first kind; then, grasping the inferior angle of the scapula with the other hand, he raises that bone and gives it a seesaw motion, which is speedily followed by a return of the articular surfaces to their natural relations. In the forward dislocation of

the humerus, the angle of the scapula is elevated and directed outwards; while in the backward luxation it is directed inwards. If any difficulty is experienced in effecting the reduction, the arm is confided to an assistant, but in general this is unnecessary, the manipulations of the surgeon alone being quite sufficient. Vincent, Skey, and others have occasionally succeeded in effecting reduction by placing a hard cylinder, as an iron knob, a porter-bottle, or a piece of wood into the axilla, and bending the arm over it across the chest.

Complicated Dislocations.—Luxation of the shoulder is sometimes complicated with fracture of the acromion, the neck of the scapula, or the superior extremity of the humerus. When this is the case, the rule is to reduce the dislocation, and then to set the fracture, the limb being put up temporarily in splints, as it will thus afford a better leverage for the management of the displaced bone. A fracture of the humerus in which this bone is severed at its surgical or anatomical neck is occasionally met with, and is a very serious occurrence, rendering the reduction one of extreme difficulty. In such a case our main reliance must necessarily be upon pressure, applied with the thumbs and fingers aided, perhaps, by fillets, while extension and counterextension are made in the usual manner. Displacement of the head of the humerus with fracture of the anatomical neck seldom admits of rectification in any case.

Compound dislocations of the shoulder-joint are rare in civil practice. When the head of the humerus is forced through the soft parts, no time should be lost in restoring it to its natural position, provided it has not sustained any serious detriment, when it should promptly be excised, so as to afford the patient a better chance of recovery.

Laceration of the axillary artery, followed by a diffused aneurism, sometimes complicates this accident. The prominent symptoms are, cessation of pulsation at the wrist, and the sudden formation of a large tumor in the axilla. The proper plan is at once to ligate the artery above and below the seat of rupture, and then to reduce the dislocation, provided it can be done safely. In a case related by Mr. Robert Adams, in which this was done, the patient made an excellent recovery. Dr. J. C. Warren was compelled to tie this vessel on account of an enormous aneurism, the result of injury inflicted by the surgeon's boot in an effort to effect replacement in a recent dislocation.

Anomalous Dislocations.—Malgaigne, in 1849, described, under the name of *supra-coracoid*, a luxation, at that time considered as unique, in a man, sixty-eight years of age, in which the head of the humerus was thrown forwards and upwards, above the coraco-acromial ligament, in contact with the inner border of the acromion. It rested upon the coracoid process, touched the lower surface of the clavicle, and formed a prominent projection immediately beneath the deltoid muscle. The arm was slightly shorter than natural. In a more recent case, under the care of Mr. T. Holmes, in a man, fifty years of age, who had fallen from a great height upon a heap of stones, the head of the bone had escaped from the glenoid cavity of the scapula, and lay upon the stump of the coracoid process, broken in the accident. It extended as high up as the clavicle and the coraco-acromial ligament, and, having passed through the fibres of the deltoid muscle, was covered merely by the skin. The long tendon of the biceps retained its attachment to the scapula, but was pushed to the outer side of the head of the humerus, which was twisted somewhat upon its axis. An example, apparently of a similar kind, has been recorded by Mr. Prescott Hewett.

Dr. Willard Parker, in 1852, met with a luxation of the shoulder-joint, in which the head of the humerus was thrown into the *subscapular fossa*, in a young man twenty years of age, whose right arm was caught between the belt and drum in a woolen factory, and violently rotated outwards, while the machinery was in rapid motion. When the limb was liberated, it was found lying diagonally across the body, in a state of strong, fixed pronation; the rotundity of the shoulder was lost; and the head of the bone could be distinctly felt beneath the scapula. The reduction was effected by carrying the arm outwards at a right angle with the body, and then pulling the hand and wrist, so as to force the humerus into the axilla, whence it was afterwards easily raised into its proper situation.

In a dissecting-room specimen, fig. 677, in my cabinet, the head of the humerus is thrown forwards, and lodged under cover of, and partly above, the clavicle, in contact with the costal surface of the scapula. The accident was accompanied by a fracture of the coracoid process, which is hooked over the head of the humerus. The shoulder was permanently ankylosed, and the arm hung stiffly along the side of the chest.

Larrey has described a preparation, in which the head of the humerus had penetrated the chest, through the third intercostal space, so as to form a tumor within its cavity.

The accident was produced by a fall upon the elbow, separated at the moment from the side of the body.

In a case reported by Laugier, the bone was turned directly forwards, resting against the outer margin of the coracoid process. The great tuberosity corresponded to the glenoid cavity, and the limb had a remarkably twisted appearance.

The reduction in these anomalous dislocations is effected upon the same principles as in the more ordinary forms of the accident. As there is usually extensive laceration of the soft parts, the operation is generally a very easy one, although it may be very difficult to keep the head of the bone in place, especially when the accident is associated with fracture of the coracoid process or the glenoid cavity of the scapula. In a case of dislocation of the head of the humerus against the coracoid process, of eleven weeks' duration, in a man, thirty-two years of age, Professor T. G. Richardson promptly effected reduction by raising the limb perpendicularly on a line parallel with the body while he steadied the acromion process with his foot. Having maintained this position for a few minutes, the arm was brought quickly down over an assistant's hand placed as a fulcrum in the axilla.

Double Dislocations.—Finally, there is occasionally a simultaneous dislocation of both shoulder-joints. Such an accident, however, of which interesting cases have been reported by W. H. Van Buren, Geddings, Cowper, T. W. Grosvenor, and others, is exceedingly uncommon. The head of each bone is generally forced down into the axilla, or one occupies this situation and the other the chest beneath the pectoral muscles. The dislocations which are sometimes complicated with fracture of the scapula, humerus, or clavicle, are usually caused by a fall, in which the person stretches out both hands to save himself from injury. In a case treated by Ballingall, the accident occurred during an epileptic fit; and in another, recorded by Nathan Smith, in an attack of puerperal convulsions. I am cognizant

Fig. 677.

Anomalous Dislocation of the Shoulder-joint.

of two cases of simultaneous dislocation of the shoulder-joint, one of them having occurred in my own practice, in which the head of the humerus was thrown into the axilla in attacks of epilepsy.

The reduction in the double dislocation is effected upon the same general principles as in the single variety. In Smith's case, replacement was effected at the end of seven months. In a case recorded by Fischer, the patient, a stout, athletic man, restored the parts by his own efforts. Seating himself upon a high bench, he seized, simultaneously with both hands, a transverse beam above his head, and, throwing himself suddenly and forcibly from his seat, both bones instantly slipped into the glenoid cavities with a crackling noise. In Van Buren's case, the man died in five hours after the accident, from injury of the skull and brain.

After-treatment.—The after-treatment of dislocations of the shoulder requires special attention. In the first place, it is highly important to guard against a recurrence of the accident, which is so liable to happen after all injuries of this kind, especially after luxation into the axilla. Generally, all that is necessary for this purpose is to support the elbow, forearm, and hand for some time in a sling close to the side of the body; or, if the patient be restive, the arm may be secured to the trunk, over a small pad, by six or eight turns of a bandage. Full elevation, abduction, and rotation of the limb should not be permitted for five or six weeks, or until there is reason to believe that the capsular ligament and muscles have been in great degree repaired. Inflammation is treated upon ordinary principles.
Dislocations of the shoulder are particularly liable to be followed, despite the best directed efforts of the surgeon, by atrophy of the deltoid muscle and by more or less permanent rigidity of the articulation. To counteract these occurrences, passive motion should be instituted as early as possible after the receipt of the injury, and perseveringly continued until the parts are completely restored to their normal condition. When, as occasionally happens, the rigidity is dependent upon contraction of the neighboring muscles, especially the great pectoral and broad dorsal, it may be promptly overcome by the free subcutaneous division of the resisting fibres with the tenotome. The atrophy of the deltoid may sometimes be relieved by electricity and by frictions with veratria liniment.

One of the most disagreeable and perplexing occurrences after the reduction of a dislocation of the shoulder is the difficulty of keeping the parts in their natural relations. This circumstance may be due to several causes, the most frequent of which are, fracture of the margins of the glenoid cavity, and the rupture of some of the muscles of the joint, in consequence of which the head of the humerus, the moment it is left to itself, falls away from the scapula into some abnormal situation, generally down into the axilla, by the mere force of the weight of the arm. Such an event is always very annoying, inasmuch as it is apt to induce the belief, on the part of the patient and his friends, that the reduction was not perfectly effected. The best remedies are rest and proper support of the affected parts, followed, in due time, by passive motion and other means for combating rigidity and ankylosis.

Accidents.—Dislocations of the shoulder are sometimes followed by paralysis of the deltoid muscle, from injury done to the circumflex nerve by the head of the humerus. Occasionally the axillary plexus suffers very seriously, and then the paralysis may be much more extensive, involving, perhaps, the whole arm, as in two cases reported by Professor Dugas. When the lesion is slight, it may disappear spontaneously, or with the aid of stimulating liniments, veratria ointment, and counterirritation, especially vesication; but in its more severe forms, as when it depends upon contusion and partial disorganization of the nerves, it often proves very refractory, and may even be incurable.

Another unpleasant effect which now and then succeeds dislocations of the shoulder, is œdema of the corresponding extremity, arising from the pressure of the head of the humerus upon the axillary veins and lymphatics; this, however, rarely lasts beyond a few days, and generally disappears spontaneously or under very simple means.

A sudden development of emphysema, first noticed by Desault, is sometimes met with after this accident, and is well calculated to create unpleasant apprehensions in the mind of the attendant. It is evidently caused by a wound of the chest, from fracture of a rib, penetrating the pleura and lung, as is proved by the fact that the starting point of the air is always under the pectoral muscle, from which it rapidly spreads to the axilla and to other parts. It may readily be distinguished from an extravasation of blood, consequent upon rupture of the axillary artery, by its elasticity, by the continuance of the pulse at the wrist, by the natural appearance of the skin, and by the production of a crackling noise when the part is pressed with the finger. Astringent lotions and gentle compression are the proper remedies.

Finally, the accident is sometimes attended with rupture of the axillary artery, leading to copious infiltration of blood, or, when the lesion affects only the inner tunics of the vessel, to the formation of a false aneurism. In the former case, the proper treatment is ligation of both ends of the vessel; in the latter, of which a remarkable instance has been recorded by Nélaton, after the reduction of the luxation, the subclavian artery should be tied. In an instance of subcoracoid dislocation observed by Bérard, in which there was no pulsation at the wrist after the accident, several of the fingers were attacked with gangrene, followed by the death of the patient. The internal coats of the axillary artery were torn across in their entire circumference, and the outer one greatly stretched.

Old Dislocations.—Old dislocations of the shoulder are often brought under the notice of the surgeon, and the question, therefore, arises, at what period after their occurrence should he refrain from an attempt at reduction? Upon this subject I do not think it possible to lay down any definite rules. I have myself been foiled at the end of the sixth week, and have known other practitioners of great skill and experience to be equally unfortunate. On the other hand, I succeeded in one case at the end of the seventy-second day, and in another at the expiration of the third month. Physick succeeded in a number of instances after two and three months; and examples of from four to seven months' standing have been reported by McKenzie and Jameson, of Baltimore, Dorsey and Gibson, of this city, and by other American surgeons. Dr. Nathan Smith effected reduction in one case nearly one year after the occurrence of the accident. Keppell is

said to have succeeded at the end of fourteen months, and Dieffenbach at twenty-four, not, however, without the extensive division of the capsular ligament and adjoining muscles. These instances are certainly very encouraging, but they should, nevertheless, be received with great caution, especially when it becomes necessary to view them as examples for our imitation. It should not be forgotten, as stated elsewhere, that the greatest possible differences prevail in regard to this subject; that in one case a dislocation may become irreducible in several weeks, and in another not under several months, depending upon the individual circumstances of each.

Perhaps the best plan that can be adopted in these chronic cases is to be guided by the degree of motion that has been acquired by the luxated bone. When this is considerable, it may be assumed that it has succeeded in establishing for itself a new joint, which it might be dangerous to disturb on account of its important relations with the surrounding parts. Another consideration which should have its weight is the amount of inflammation by which they are followed; if this has been unusually violent, it may be inferred that there has been copious plastic effusion, filling up the original socket, and causing extensive adhesions among the muscles and vessels, matting them firmly together, and rendering interference hazardous. Interference would also be particularly dangerous in subjects laboring under atheromatous degeneration of the arteries.

When it is deemed advisable to attempt reduction, a certain amount of preliminary treatment should always be instituted, with a view of facilitating the breaking up of the abnormal adhesions between the head of the displaced bone and the surrounding parts, so as to lessen the danger both of failure and of injury to the axillary vessels and nerves, after the application of the extending and counterextending forces. The method of reduction by traction upwards, generally known as that of Moth, is to be especially avoided, as it is more liable to be followed by laceration of the axillary artery than the more common procedures.

Manipulation is beyond question the safest mode of procedure in neglected dislocations of the shoulder, especially when the parts have not remained out of place longer than five, eight, or ten weeks. A good plan, one that has often succeeded under such circumstances, is, after the adhesions have been broken up by rotation and circumduction, to extend the limb at a right angle with the chest, while the trunk is steadied with a sheet, and then bringing the elbow suddenly and forcibly to the side of the body, over the arm of the surgeon placed near the axilla. During this manipulation, the head of the bone, if not too strongly impacted, slips readily into the glenoid cavity of the scapula. The employment of pulleys in such cases is generally worse than useless, while that of Jarvis's apparatus is fraught with danger to limb and life.

Notwithstanding the greatest care that can be exercised in these operations, the issue is occasionally most disastrous. The accidents that are most liable to occur are, severe contusion of the soft parts, fracture of the humerus, and laceration of the axillary artery. A number of instances have been related in which death was produced either by shock or by the severity of the resulting inflammation.

The skin and muscles must often, of necessity, be much bruised, and the latter sometimes even partially lacerated, in these operations. The occurrence may be brought about simply by the long-continued pressure of the heel in the axilla, or by the use of special apparatus, and is not unfrequently attended with extensive abrasions of the surface and more or less infiltration of blood in the connective tissue of the axilla and side of the chest. Occasionally large abscesses form in and around the joint.

The axillary artery has been ruptured in a considerable number of instances, and the result, in nearly all, has been promptly fatal. The disastrous cases recorded by Verduc, Petit, Leder, Delpech, Cooper, Pelletan, David, Flaubert, Bell, Gibson, Blackman, Lister, and others are well known to surgeons, and should serve as warnings in regard to rude and protracted interference in accidents of this kind, sometimes even when they are not of long standing. That such an occurrence should happen is not at all singular when it is recollected how liable dislocations of the shoulder are to be followed by severe inflammation and copious deposit of lymph, firmly gluing the axillary artery to the surrounding parts, and thus necessarily endangering it in any forcible attempts that may afterwards be employed to restore the head of the humerus to its natural position. The necessary result of such an injury is, of course, an aneurism, generally of a diffused nature, and characterized by the ordinary phenomena, as the sudden formation of a tumor in the axilla, and the cessation of pulsation at the wrist.

The circumscribed form of aneurism is uncommon as an effect of this accident. Two typical cases of it have been recorded by Dupuytren and Nélaton, in each of which a con-

siderable period elapsed before the tumor attained much bulk. In the former the swelling was mistaken for an abscess, which was opened by mistake, and followed by fatal hemorrhage. In the other case, that of an old woman who had a subglenoid luxation that was easily reduced, the subclavian artery was ligatured.

The axillary vein has sometimes been lacerated. Froriep has related an instance of this kind in a woman twenty-six years old. The axilla became suddenly enormously distended with blood, and death occurred within an hour and a half. The dislocation had existed only twenty days. Professor Agnew, of this city, has reported a similar case as having occurred in a woman sixty years of age. The dislocation had existed only six weeks. Perfect recovery ensued.

Of 19 cases of rupture of the axillary artery, in efforts to reduce old luxations of the shoulder-joint, analyzed in 1873, by Dr. Willard, of this city, 12 proved fatal, 6 recovered, and of 1 the result is not known. In 3 of these cases, the axillary artery was tied, in all without benefit; and the subclavian in 4, with 2 recoveries. Rupture of the axillary vein and artery together happened in 3 cases, 2 of which ended unfavorably, the result of the other not being stated.

A number of instances of laceration of the axillary nerves have been reported as having occurred in attempts to reduce old dislocations of the shoulder. The accident is necessarily followed by more or less paralysis of the superior extremity. A more common effect is severe contusion of these cords, with pain and œdema of the limb, and temporary impairment of function.

Fracture of the humerus has occurred in the hands of some of the most distinguished surgeons. The portion most liable to give way is the surgical neck, and the accident always happens during the violent efforts that are made to force the head of the bone out of its abnormal position while the arm is pressed forcibly across the chest, the strain thus produced being concentrated at the superior extremity of the humerus. The event is generally indicated by a loud noise or snap.

It is not improbable that in a very old person the ribs might be fractured in efforts of this description by the pressure of the heel in the axilla or by the use of Jarvis's adjuster. One such case was recently reported by Mr. Teevan, of London.

The immediate effects of such accidents, especially of rupture of the axillary artery and vein, either singly or conjointly, are generally followed by excessive prostration, deadly pallor of the countenance, clammy sweats, feeble respiration, and cessation of the pulse at the wrist. To meet such contingencies powerful stimulants and even the use of the electric battery may be necessary. When the axillary artery is ruptured, the most correct plan is at once to expose it by a free incision, and to ligate it at each extremity, as in aneurism of a similar nature in other parts of the body. When the tumor is circumscribed, and of slow formation, ligation of the subclavian artery, as practised by Gibson, Warren, and Nélaton, would be proper. Large extravasations of blood in the armpit even if produced by rupture of the axillary vein, generally readily disappear under the influence of sorbefacient remedies, especially strong solutions of chloride of ammonium.

The constant and excessive suffering which sometimes attend an unreducible dislocation of the shoulder-joint, from the pressure of the humerus upon the brachial plexus of nerves, can only be relieved by the excision of the head of the bone; an operation which, so far as I know, was first performed in 1860 by Professor Edward Warren, formerly of Baltimore, now of Paris. His patient was a female, fifty years of age, who, twelve months previously, in a fall, had luxated the humerus, throwing it down into the axilla beneath the coracoid process in contact with the brachial plexus of nerves, occasioning violent and persistent pain, with great debility and gradual emaciation. The joint was exposed by a V-shaped incision, and the head of the bone, firmly wedged in its new position, divided through the surgical neck. The patient rapidly recovered with a good use of the arm. The precedent set in this case has been followed by other surgeons, as the only operation that holds out any chance of relief from the frightful suffering entailed by such an accident. When the head of the humerus is so firmly fixed in its acquired position as to render the corresponding limb completely useless, the most rational plan is to divide the bone subcutaneously through its neck, with a view of establishing an artificial joint. This can be readily done by means of an Adams's saw, with the precaution of avoiding the brachial artery and axillary plexus of nerves. In a case of luxation of the shoulder-joint of fourteen months' duration in a man thirty-eight years of age, Dr. J. Ewing Mears, in 1875, performed an operation of this kind with very gratifying results, the patient, when last seen, nine months thereafter, having an excellent use of his limb. Passive motion, long continued, after all such pro-

cedures, is an indispensable condition of the treatment. When the operation fails excision of the head of the bone is the only resource.

Congenital Dislocations.—Congenital dislocations of the shoulder-joint have been particularly studied by Mr. Robert W. Smith, who directed special attention to them in his excellent work on fractures published in 1847. Since then they have been examined with much care by Gaillard, Guérin, Nélaton, and others.

The malposition, which may be single or double, sometimes coexists with similar displacement in other articulations. Only two varieties have hitherto been recognized by dissection, termed, by Mr. Smith, the subcoracoid and the subacromial, the head of the humerus in the former being lodged beneath the coracoid process, and in the latter on the dorsal surface of the scapula, below the outer and posterior part of the acromion. The latter might, perhaps, more properly be called the infraspinous form of the luxation.

The symptoms of both these dislocations are well marked. In the subcoracoid variety, the shoulder has a flattened appearance, especially at its upper and posterior aspect, the acromion is unnaturally sharp and prominent, there is a remarkable hollow in the supraspinous fossa, and the head of the humerus may readily be felt beneath the coracoid process, forming a distinct ball, which promptly obeys the movements of the elbow. The arm, which hangs along the side, is greatly withered, thus singularly contrasting with the forearm and hand, which generally retain their full development, being in fact quite as well conditioned as those of the opposite limb. The movements of the scapula are perfectly normal, while those of the arm are either annulled, or very much impeded, especially abduction; the forearm can be bent, but not actively extended. The movements, on the contrary, of the hand and fingers, are nearly, if not entirely, natural.

In the subacromial dislocation the head of the humerus may easily be felt on the dorsum of the scapula, a short distance below the root of the acromion, where it forms a distinct, unmistakable prominence. The deltoid muscle is flattened externally and in front; the acromion is uncommonly salient; the arm, shortened and withered, is rotated inwards towards the trunk; and the forearm and hand are slightly pronated, supination being executed with great difficulty.

Dr. Rodrigue, of Pennsylvania, has reported an instance of intrauterine dislocation of the shoulder-joint complicated with fracture of both bones of the forearm, caused by a fall of the mother near the middle term of pregnancy. The head of the humerus lay in the axilla, and could not be restored to its normal position.

The treatment of these dislocations must be conducted according to the general principles laid down in a previous page. In a remarkable instance, Gaillard succeeded in effecting the reduction of a congenital luxation of the shoulder-joint in a girl sixteen years of age, who recovered with a most excellent use of the arm. For several weeks prior to the operation, the parts were daily subjected to passive motion and manipulation, so as to induce them to yield the more readily to the necessary extension and counterextension. The inflammatory symptoms that followed the reduction were combated by the usual means.

Dislocation of the Tendon of the Biceps.—The tendon of this muscle is liable to be dislodged, by being violently wrenched from its bed in the humerus, and, perhaps, partially torn, if not completely snapped asunder. In the latter case, the upper extremity of the tendon may float loosely about within the joint. The accident generally happens from falls or blows upon the shoulder, forcing the humerus away from the glenoid cavity of the scapula, generally upwards and inwards against the coracoid process, or forwards against the ribs. It may also occur from

Fig. 678.

Dislocation of the Tendon of the Biceps Muscle.

falls on the hand or elbow, especially if, at the moment, the limb is very much twisted upon its axis. The nature of the lesion is always obscure, and, therefore, very apt to be overlooked or to be mistaken for fracture, sprain, or dislocation of the shoulder. The most reliable symptoms are, inability to flex the arm from the loss of power in the biceps, and pain at the seat of the injury, either alone, or in conjunction with more or less prominence of the head of the humerus. Reduction should be attempted by thorough

relaxation of the affected muscle by bending the forearm at a right angle with the elbow, and then pressing the tendon back into its proper place with the fingers. The after-treatment should be strictly antiphlogistic, otherwise there will be great danger of permanent ankylosis of the joint. If the tendon is completely severed, the limb will always be weak. In the adjoining drawing, fig. 678, from a preparation of Mr. Sodon, the tendon of the muscle lay with its sheath on the lesser tubercle of the humerus.

3. INFERIOR EXTREMITY.

DISLOCATIONS OF THE FOOT.

Luxations of the *phalangeal* and *metatarso-phalangeal* joints are uncommon, and are mostly of so complicated a character as to require amputation. The reduction is always easy.

Of dislocation of the *great toe* at the metatarsal joint, a very infrequent accident, I have seen two cases, one recent and the other old. The following is a brief history of them.

A gentleman, forty-two years of age, struck the dorsal surface of the foot against a lump of coal, bending the great toe downwards and dislocating it at the metatarso-phalangeal articulation. The accident, which caused considerable pain, was so well marked as to be at once recognized. The toe, inclined somewhat outwards, lay a little higher than in the natural state, and was fully half an inch shorter than the sound one. The head of the first phalanx rested upon the dorsal surface of the anterior extremity of the metatarsal bone, where it formed an abrupt, well-defined prominence. The projection on the plantar surface, formed by the head of the metatarsal bone, was less conspicuous. The adductor muscles of the great toe formed a broad, tense cord at the inner side of the foot. I saw the man within an hour after the accident, before there was any swelling or discoloration of the parts; and having placed him under chloroform, I readily drew the toe into its proper position with the aid of a narrow roller secured with a clove-hitch knot, the extension being made forwards and slightly downwards, to disengage the head of the phalanx from the anterior extremity of the metatarsal bone. The foot was steadied by an assistant grasping the ankle.

In the other case the foot was caught between two steamers, which twisted off the man's boot, severely wrenching the limb, and bruising the soft parts. The phalanx of the big toe was forced below the metatarsal bone, forming a large prominence in the sole of the foot, which has ever since, now a period of six years, been a source of much annoyance, being frequently so sore and tender as to interfere materially with progression. In such a case resection or amputation would be the proper remedy.

The reduction of this luxation is occasionally attended with considerable difficulty, depending probably upon the manner in which the adductor muscle and the sesamoid bones are dragged by the displaced phalanx backwards over the extremity of the metatarsal bone. In the event of such a contingency an attempt might be made to effect restoration by means of Dr. Crosby's plan of reducing dislocations of the thumb, raising the toe perpendicularly, and then applying strong pressure against its base, so as to push it from behind forwards, and from above downwards.

An instance, so far as I know a solitary one, of dislocation of all the toes from the metatarsal bones, has been recorded by Josse, of Amiens, the patient being a dragoon who, in a fall from his horse, struck his foot against the ground, forcing the bones outwards. The reduction could only be effected after the removal of the head of the first metatarsal bone, which projected through a wound in the skin.

The *metatarsal* bones are rarely dislocated, owing to the firmness of their connections with each other and with the lower row of tarsal bones. The accident is most commonly compound. A simple luxation, however, of one or more of these bones, is sometimes occasioned by a violent wrench of the foot, or by the passage of the wheel of a carriage, as happened to me in a case, many years ago, in which the fourth and fifth metatarsal bones were detached from their connections with the cuboid bone, and thrown upwards upon the tarsus. The reduction was effected with great facility, and, under the employment of leeches and other antiphlogistics, the man was able in the course of a fortnight to exercise on crutches, regaining eventually a good use of his limb.

The only case of a complete dislocation of all the metatarsal from the tarsal bones of which I have any knowledge, was communicated to me by Dr. Traill Green, of Easton, Pennsylvania, as having occurred under his observation and that of Dr. Edward Swift. The patient, a man, sixty-five years old, in falling down a flight of stairs, injured the

left foot, which was found soon after the accident to be much swollen over the arch and very painful, with deformity at the inner and outer edge. The metatarsal bone of the great toe was separated from the internal cuneiform bone, and thrown over towards the outer margin of the foot, leaving the latter bone quite prominent at the inner side. A similar condition existed on the opposite side, the metatarsal bone of the little toe being thrown off completely from the cuboid bone, so as to present a well-marked projection at the outer border of the foot. In short, the twisted state of the foot, the great deformity, and the swelling of the arch, clearly indicated a lateral displacement of all the metatarsal bones.

The reduction was easily effected. The patient being placed in a half-reclining posture on a settee, with his right foot against the arm, to brace himself during the operation, an assistant applied his knee to the instep, and while he made extension by grasping the dislocated portion of the foot, previously surrounded by a wet roller, to prevent the lac from slipping, Dr. Green, who supported the leg upon his thigh, made strong lateral pressure, in a direction contrary to that of the displacement. The parts soon began to yield, and in a few minutes returned to their proper place with a distinct snap, all deformity at the same time disappearing.

Dislocation of the *tarsal* joints is uncommon, their limited motion and the strength of their ligaments forming so many obstacles to their disunion. The astragalus is almost the only bone which is liable to displacement, and this accident is also unusual.

Dislocation of the *cuneiform* bones is extremely infrequent. The internal one is most liable to suffer. The accident, of which a well-marked case has been reported by Dr. Vedder, of Elmira, New York, is usually caused by falls from a considerable height, in which the person alights upon the sole of the foot, the force separating the bone from its natural relations. A projection on the inside of the foot, and a slight elevation of the bone, from the action of the anterior tibial muscle, are the characteristic signs of the lesion. The reduction, which is difficult, is effected mainly by pressure. In two cases of this luxation, mentioned by Sir Astley Cooper, replacement was found to be impracticable. When this happens, the patient, notwithstanding, generally, in time, regains a tolerably good use of the limb.

Retention is maintained by adhesive strips, a compress, and bandage, aided by splints, to keep the foot in a quiet, easy position. When the inflammation has sufficiently subsided, a leather strap with a soft pad should be worn, to protect the parts until the reparative process is completed.

The *scaphoid* and *cuboid* bones are occasionally separated from their connections with the astragalus and calcaneum, in consequence of the falling of a heavy weight, or of a person jumping from a considerable height and alighting upon the sole of the foot. Under these circumstances the foot is shortened, and twisted upwards and inwards, forming a remarkable prominence upon the instep, which gives it a distorted appearance not unlike what occurs in varus. The accident, which is extremely infrequent, is easily remedied by fixing the leg and heel, and then drawing the toes outwards, in a direction contrary to that of the displacement. Suitable retentive means will be required to prevent a recurrence of the luxation.

The *calcaneum* may be dislocated from the cuboid bone laterally, in an outward direction, by causes similar to those producing displacement of the other tarsal bones. The accident is easily detected and remedied by manipulation.

A remarkable instance of dislocation of the five anterior *tarsal* bones from the astragalus and calcaneum has been recorded by Sir Astley Cooper, as having occurred in a laboring man, from the fall of a very heavy stone. The foot was singularly distorted, exhibiting very much the appearance of clubfoot, the forepart being turned inwards upon the astragalus and calcaneum, so as to give the limb an arched shape. The reduction was easily effected by fixing the leg and heel, and pushing the luxated bones in a direction contrary to that of their displacement. A similar case has been recorded by Petit.

Dislocations of the *astragalus* occur under two varieties of form, the partial and the complete; in the former, as the name implies, the bone still retains some of its connections with the tibia and fibula, or the calcaneum and scaphoid, whereas in the latter the connections are entirely lost, complete disruption having taken place, or, in other words, the bone is lifted bodily out of its original position into one altogether new. It is obvious that such an accident can only occur from the application of excessive violence, in which the foot is strongly extended upon the leg, and more or less rotated upon its axis. Hence it is always of a grave nature, and rarely unaccompanied by fracture of the

inferior extremity of the tibia and fibula, which thus adds still further to its complications and dangers. Occasionally, indeed, the astragalus itself is severely shattered.

Dislocation of the astragalus may take place in two directions, backwards and forwards, the latter, which is by far the more frequent, admitting also of a certain degree of displacement laterally, or to either side, in consequence of a twist of the foot. In the posterior luxation the bone does not experience any rotation, and is, therefore, more in the course of the median line, suffering no material lateral deviation. Authors describe two lateral dislocations of the astragalus, but such a displacement can, for obvious reasons, occur only in connection with fracture of the tibia and fibula, or of both these bones.

In the luxation *backwards*, of which only a few cases have been reported, the astragalus is thrown behind the ankle, resting upon the superior surface of the calcaneum, where it forms a large, characteristic prominence. The tendo Achillis is pressed strongly backwards by the displaced bone, there is great tension of the skin of the heel, the muscles of the calf are very rigid, the tibia is slightly pushed forwards, and the instep appears a little shorter than natural. In general, also, there is a slight vacuity in front of the joint. Both the tibia and fibula are sometimes fractured.

The reduction is attended with extreme difficulty, owing to the manner in which the surfaces of the astragalus and calcaneum are interlocked with each other, and I am not aware that the operation has ever succeeded, except in one case, which occurred to Mr. Liston, and in which the accident was attended with fracture of the tibia and fibula, which had probably the effect of rendering the parts more movable. In attempting to replace the bone, the leg and foot should be as strongly flexed as possible, so as to induce thorough relaxation of the gastrocnemial muscles, and then, while extension and counter-extension are made by means of the clove-hitch, the astragalus should be urged from behind forwards into its natural position. When the difficulty is very great, the parts absolutely refusing to yield to any efforts, however judiciously applied, the only thing to be done is the subcutaneous section of the tendo Achillis; an operation which has occasionally proved successful.

When reduction fails, the patient will in time acquire a tolerably good use of his limb, the parts accommodating themselves gradually to their new relations. In one instance, where the attempts proved unsuccessful, the bone caused sloughing of the soft structures, and was obliged to be extracted.

The luxation *forwards* is generally incomplete, the anterior half of the bone, or a little more, resting upon the dorsal surface of the scaphoid bone, while the posterior half is imbedded in the hollow between the two articulating surfaces of the calcaneum. The displaced bone forms a distinct prominence over the instep, while a marked vacuity exists at the inner part of the foot, just below the corresponding malleolus. The tibia and fibula either retain their natural position, lying upon the posterior surface of the astragalus, or, as more commonly happens, they are carried slightly forwards, thus increasing the length of the heel, and inclining the foot towards one side or the other, according to the peculiar relations which the bone may sustain towards the calcaneum, a trifling change of position being capable of determining the nature of the lateral displacement.

In the complete form of the accident, the bone is forced away entirely from its natural position, being tilted up in front of the joint so as to rest upon the scaphoid and cuneiform bones. The signs are characteristic, the large prominence at the instep, the constrained and twisted position of the foot, the shortening of the leg, and the descent of the malleoli towards the sole of the foot, together with the elevation and lengthening of the heel, being sufficient to reveal its nature at a glance.

Sometimes the position of the astragalus is almost completely reversed, and there are few cases in which the displacement is unattended with fracture of the tibia and fibula, or even of the astragalus itself. Moreover, the dislocation is not unfrequently compound, the soft parts being severely lacerated, and the wound extending into the ankle and tarsal joints; or, when such an effect has not been the direct result of the accident, the foot is soon reduced to that condition by the ulceration and sloughing caused by the pressure of the displaced bone upon the integument of the instep.

The great obstacle to reduction in this as in the backward dislocation is the malposition of the astragalus, or the change in its axis, which not unfrequently baffles all the efforts of the surgeon at restoration, however well directed or perseveringly continued. Even when the displacement is only partial, the difficulty will generally be very great, although less than in the complete form, in which it is usually insurmountable. In the latter case, indeed, it is questionable whether, after what experience has taught us, it would be judicious to make any efforts at reposition, seeing how much all such trials,

rough and protracted as they necessarily must be, must tend to aggravate the injury, and increase the risk of undue inflammation. When the displacement is partial, immediate recourse should be had to reductive means, consisting of traction and pressure, aided, if the case prove rebellious, by the subcutaneous section of the tendo Achillis and of any ligaments that may seem to act obstructingly. When replacement is impracticable, the tension of the parts should be relieved by subcutaneous incisions, as this will lessen the risk of sloughing and exposure of the bone; a circumstance inevitably productive of necrosis, and the necessity of partial excision. When such an accident can be prevented, it is consolatory to know that, as in the dislocation backwards, the osseous surfaces become gradually adapted to each other, thereby ultimately permitting a tolerably good use of the limb.

When the bone is entirely displaced, lying immediately beneath the integument and muscles of the instep, the only safe procedure is immediate excision, the ends of the tibia and fibula being placed in the sulcus vacated by the removal of the astragalus, and the edges of the wound being carefully approximated by collodion, so as to insure their prompt reunion without the risk of suppuration. Statistics strongly testify in favor of this plan of treatment. Thus, of fifty-two cases analyzed by Broca, forty-two terminated successfully. The operation, however, is not always free from difficulty, as is exemplified in an instance recorded by Dupuytren, in which the bone was extirpated only after a long and tedious dissection, owing to the pulley-like surface of the astragalus being turned downwards, while its posterior projecting part was hooked in under the tibia. Only about one person in four recovers with ability to move the ankle after such an accident.

A very curious luxation of the astragalus is occasionally seen, originally described by Malgaigne under the name of *substragaloid*, in which this bone is forcibly wrenched from the calcaneum and scaphoid but retains its normal relations with the tibia and fibula. The lesion, which is fortunately of rare occurrence, is also known as the astragalo-calcaneo-cuboid dislocation. Falls from some height in which the part as it strikes the surface is twisted more or less on its axis, are the most common causes of the accident. In a case under my observation in 1880, the patient, a young man, fell off a ladder a distance of about eight feet, upon the floor. When seen an hour after the accident the foot presented very much the appearance which it has in valgus, that is, it was twisted or rotated on its axis and considerably shortened; the outer border was turned upwards, while the inner was greatly depressed, and scooped out as it were. The heel and the toes retained their normal appearance. There was some pain but no swelling of any account, and the bones were immovably interlocked with each other. Various attempts were made at reduction, but the bones yielded only in a very slight degree, and the case was finally abandoned as hopeless. No grave symptoms ensued; and when the patient was last seen, nearly one year after his mishap, he walked with the aid of a properly constructed shoe so well that the slight halt in his gait was hardly noticeable. The difficulty which attends the reduction of this luxation is due, in great degree, if not entirely, to the manner in which the sharp facets of the astragalus are wedged into the cavities of the calcaneum and scaphoid bone. Some impediment may possibly also be caused by the unnatural position into which the tendons of the posterior tibial and plantar muscles are thrown. The division of the tendo Achillis does not seem to help the matter any, and cannot, therefore, be regarded as a factor in the difficulty of effecting reposition. The pulleys might be employed in such a dislocation, but if another case of the kind should come under my observation, I should certainly be inclined to give a fair trial to Mr. Henry Lee's plan, which consists in making extension by means of a fillet fastened in the form of a clove-hitch knot around the anterior portion of the metatarsus, and throwing the noose over the shoulder of the surgeon, while counterextension is made with the knee in the concavity in front of the ankle by pressing against the lower extremity of the leg. The reduction will be materially facilitated if, while these forces are in operation, the astragalus be pushed alternately forwards and more or less laterally by an assistant,

Fig. 679.

Compound Dislocation of the Astragalus Inwards

as in the interesting case of subastragaloid luxation reported by Mr. Pick in the thirteenth volume of the Transactions of the Clinical Society of London.

In *complicated* dislocations of the astragalus, fig. 679, a similar procedure is proper; but here, if the injury be at all grave, the question of amputation will necessarily arise, and much judgment will generally be required to make a just decision. In all severe cases, involving extensive lesion both of the soft structures and of the bones, especially when occurring in weakly or sickly subjects, no experienced surgeon would for a moment hesitate as to the propriety of removing the limb; the only doubt that could possibly arise would be, whether the operation should be done through the leg or through the foot, according to Pirogoff's method.

The after-treatment of these cases requires no special mention. The great points are to give due support to the limb, and to moderate the resulting inflammation by the bandage, leeches, and medicated lotions; and, eventually, by the institution of passive motion to prevent union between the calcaneum and the bones of the leg. If erysipelas should appear, as in severe cases it is very prone to do, early and free incisions will be necessary.

DISLOCATIONS OF THE ANKLE.

Owing to its peculiar mechanism, dislocations of this joint are exceedingly uncommon. The length and width of the malleoli render lateral displacement of the astragalus almost impossible without concomitant fracture of one or both of these projections, while luxation in the antero-posterior direction is nearly as impracticable in consequence of the extraordinary strength and firmness of the ligaments connecting that bone to the tibia and fibula. The effect is that these injuries are almost always of a complicated character, their chief interest depending upon the violence done to the neighboring structures. Most of them, in fact, should be viewed rather as fractures of the tibia and fibula, with displacement of the astragalus, than as dislocations, properly so called, of the ankle-joint.

Luxation may occur in four different directions, forwards, backwards, inwards, and outwards. A few cases have been recorded in which the astragalus was forced upwards between the ends of the tibia and fibula; and Huguier has published the particulars of one in which the foot was turned completely outwards, the toes forming a right angle with the leg, the heel being represented by the external malleolus.

The nomenclature of these luxations has been the subject of a singular caprice, with the result of no little confusion. Instead of considering the astragalus as the dislocated bone, so as to place this joint in the same category, in this respect, as the other articulations, Sir Astley Cooper and others, adopting his example, have made it the fixed point, and the tibia and fibula the movable. This manner of viewing these lesions has occasioned a corresponding change of nomenclature, and as both are radically defective, serving only to cause embarrassment, they should be discarded.

1. Luxation *forwards*, the most infrequent of all, arises from falls on the heel, while the foot is forcibly bent upon the leg, the body being at the same time inclined forwards, so as to throw the strain upon the forepart of the joint. Under these circumstances the ligaments are extensively ruptured, and the astragalus, escaping from the mortise-like cavity of the tibia and fibula, rests immediately in front of the former bone, where it forms a large projection beneath the integument. The diagnostic signs are, the elongated state of the foot, the distance between the leg and toes being materially augmented, the remarkable shortening of the heel, and the effacement of the depressions behind the ankle from the close approximation of the tendo Achillis to the posterior surface of the limb.

The reduction is effected mainly by manipulation. As a preliminary step, the leg is flexed at a right angle with the thigh, to relax the gastrocnemial muscles, when an assistant, seizing the lower part of the leg, gradually pushes it forwards, while the surgeon, grasping the foot, and bending it considerably, forces it backwards, in the opposite direction. In rebellious cases the subcutaneous division of the tendo Achillis greatly facilitates restoration.

2. Dislocation of the ankle-joint *backwards* is caused by violence applied to the anterior extremity of the foot while it is immoderately extended, the knee being at the same time strongly flexed and projected forwards; or, the foot and leg being in this position, the accident may arise from a severe blow upon the lower and back part of the limb, the two forces driving the articulating surfaces in opposite directions. The displacement is ordinarily accompanied by fracture of the inferior extremity of the fibula.

The signs are the reverse of those in the dislocation forwards. The dorsal surface of the foot is shortened, the toes pointing downwards; the heel is elongated and firmly fixed; the tendo Achillis, pushed far back beyond its natural position, stands out in bold relief;

the pulley-like surface of the astragalus is readily perceptible at the back part of the inner ankle ; and the extremity of the tibia forms a hard prominence upon the instep, immediately beneath the integument.

The dislocation backwards is sometimes incomplete, one-half of the articular surface of the tibia resting upon the scaphoid bone and the other half upon the astragalus. The foot, pointed downwards, cannot be put flat upon the ground, and the heel is raised and abnormally prominent, but less so than in complete luxation. A careful examination of the joint will at once reveal the true nature of the case.

The restoration is accomplished in the same manner as in the luxation forwards, the gastrocnemial muscles being thoroughly relaxed, and the bones pulled and pushed in opposite directions. Any tendency that may exist to recurrence of the dislocation, must be counteracted by the division of the tendo Achillis.

Fig. 680.

Dislocation of the Tarsus Inwards.

3. Luxation *inwards* is generally occasioned by falls or blows upon the foot, in which the astragalus is violently rotated upon its axis, and thrust against the inner malleolus, which is usually broken in consequence, being separated obliquely from the extremity of the tibia, as exhibited in fig. 680. It is also liable to be produced by direct injury, as that caused by the passage of the wheel of a carriage. Sometimes the luxation is associated with fracture of the astragalus, or of this bone and the fibula, thus greatly aggravating the case. The articular surface of the astragalus, pointing immediately below the internal malleolus, can easily be perceived in its new position ; the foot is turned inwards, its outer border resting on the floor, while the inner is proportionately raised ; and there is a remarkable prominence at the outer part of the joint, formed by the extremity of the fibula. To reduce this dislocation, the leg is bent at a right angle with the thigh, and steadied by an assistant, while traction is made upon the foot, and the astragalus pushed back into its natural position.

Fig. 681.

Dislocation of the Tarsus Outwards.

4. Dislocation *outwards*, fig. 681, is the most frequent of all the displacements to which this articulation is exposed, a sudden twist of the leg, while the foot is firmly fixed, being the most common exciting cause, although it is often produce by direct violence. The articular, pulley-like surface of the astragalus is forced below the outer malleolus, and there is always fracture of the inferior portion of the fibula ; without this, indeed, the occurrence would seem to be impracticable. This form of luxation was described by most authors, until recently, as displacement inwards.

In this variety of the accident, both malleoli are sometimes broken off, the superior surface of the astragalus slipping away from the articulating surface of the tibia, and lodging in the gutter between this bone and the fibula. The foot in this case is nearly flat, as the patient stands up, with a slight upward inclination of its inner margin, and the lower extremity of the tibia forms a remarkable prominence, rendered the more conspicuous on account of the displacement of the internal malleolus, which, when broken, is always drawn over towards the fibula. Great deformity also exists at the outer border of the ankle, caused by the projection of the inferior fragment of the fibula.

The signs of this accident are unequivocal. The inner malleolus forms a remarkable projection under the skin ; the foot is twisted and easily rotated upon its axis, its inner border resting on the ground ; a depression exists on the outer surface of the leg, above the joint, corresponding with the line of fracture of the fibula, and the astragalus can be

distinctly perceived below the outer malleolus. The reduction is effected by flexing the leg strongly, so as to relax the gastrocnemial muscles, and then drawing the articulating surfaces towards each other in a direction contrary to that of their displacement. The whole procedure is one of great simplicity.

5. In the dislocation *upwards*, of which only a few cases have been recorded, the astragalus is forced upwards between the two bones of the leg, the fibula being fractured some distance above the joint, and widely separated from the tibia. The astragalus preserves its natural direction, but is so firmly impacted as to render its restoration difficult. The two malleolar projections are extremely prominent, and descend nearly as low down as the sole of the foot, which is usually inclined a little to one side. Occasionally, as in a case referred to by Mr. Druitt, fig. 682, the astragalus is thrown up between the tibia and fibula without any fracture of these bones.

In all these dislocations special attention must be bestowed upon the *after-treatment*, as they are all very liable to be followed by severe inflammation, requiring the use of leeches,

Fig. 682.

Dislocation of the Astragalus Upwards between the Tibia and Fibula.

Fig. 683.

Compound Dislocation of the Ankle-joint.

saturnine lotions, and other antiphlogistic remedies. Maintenance of the articular surfaces is effected with the aid of a fracture-box or wire case, well padded, and provided with a foot-piece, to afford complete rest to the injured structures. Passive motion must be instituted at an early period, and persisted in for a long time, otherwise ankylosis will be inevitable. Despite, however, every precaution the ankle-joint will long remain weak, if not permanently crippled.

The ankle is not unfrequently the subject of *compound dislocations*, the wound penetrating the cavity of the joint, and affecting, perhaps, the principal vessels and nerves of the limb, at the same time that there may be violent contusion of the integument, and extensive comminution of the bones of the leg. In such a case, of which a good illustration is seen in fig. 683, from a preparation in my collection, the surgeon could not hesitate as to the course to be pursued. Amputation alone can save life, and should be postponed no longer than is absolutely necessary for the occurrence of the requisite reaction. The lesion is profound, and any attempt to preserve the parts would be worse than foolish. When the injury is less violent, and the constitution sound, conservative surgery will often effect wonders, and is always worthy of a fair trial. When the ends of the bones protrude, excision will generally be the only safe course. Whatever conservative measure be adopted, more or less ankylosis will always be inevitable, although the patient may ultimately regain a tolerably good use of the limb.

The statistics of compound dislocations of the ankle-joint, attended with extensive laceration of the soft parts, clearly show that, as a rule, immediate amputation is the only safe practice. If the operation be postponed until the joint and the surrounding parts are invaded by violent inflammation, death will almost be inevitable, the patient, if he survive the dangers of erysipelas, pyemia, and tetanus, being gradually worn out by profuse suppuration, hectic fever, and constitutional irritation. Secondary amputation is seldom of any avail in saving life. Of fifty-seven cases of this kind, collected in 1877 by Dr. Frank O'Farrall, of Indiana, nearly every one perished. In ten other cases, eight of which came under his personal knowledge, in which amputation was performed at periods ranging from ten days to six weeks, only two recovered.

DISLOCATIONS OF THE TIBIO-FIBULAR JOINTS.

Dislocation of the tibio-fibular joints is an extremely uncommon occurrence; for, independently of their peculiar mode of articulation, and the great firmness and strength of

the connecting media, the resistance offered by the interosseous ligament, and the protection which the fibula receives from its relations with the tibia, are so many causes which interfere with the disruption of their surfaces. It is only, indeed, the most violent injury that can give rise to the accident. There is a form of dislocation of the upper joint which occasionally occurs as a result of excessive relaxation of the fibulo-tibial ligaments, chiefly in weakly, delicate females, allowing the head of the fibula too much latitude of motion ; but this is an occurrence very different from a genuine luxation, which is always occasioned by external force acting directly upon the component elements of the joint. Of the traumatic variety of the lesion only a few examples are on record. In a case observed by Boyer both joints were displaced simultaneously, the foot being at the same time dislocated outwards. Such an accident necessarily implies extensive laceration of the interosseous ligament, and can only happen through a fall upon the foot, or a blow upon the inferior extremity of the fibula, driving the bone upwards and outwards with the whole force of its leverage. Whatever may be the nature of the displacement, reduction is always easily accomplished by flexing the leg at a right angle with the thigh, and pushing the bone back in a direction contrary to that of its luxation. Maintenance, which is usually very difficult, must be effected by long-continued rest of the limb, and the use of a broad, elastic strap with a closely-fitting pad, acting directly upon the head of the bone.

In the *subluxation*, as it may be termed, of the upper tibio-fibular joint, the most suitable remedies are chalybeate tonics, with gentle exercise in the open air, the cold douche, electricity, tincture of iodine, a series of little blisters, and the use of a proper supporter. If the case be rebellious, a delicate tenotomy knife may be introduced subcutaneously, and carried about the joint in different directions, in order to scratch the articular surfaces, so as to provoke an effusion of plastic matter with a view of exciting obliterative inflammation.
DISLOCATIONS OF THE PATELLA.

It is obvious, from the situation of the patella and the manner in which this bone is imbedded in the tendon of the extensor muscles of the thigh, that it is susceptible of being dislocated only laterally, or outwards and inwards. Displacement downwards is impracticable, while displacement upwards cannot occur without rupture of the ligament by which this bone is connected to the tibia. Each luxation may be complete or incomplete. A remarkable form of the accident, in which the patella is dislocated edgewise, vertically, or upon its long axis, is occasionally met with. Whatever the character of the displacement may be, the occurrence is extremely uncommon. It is most frequent in thin, feeble persons, in whom it is usually produced by very trivial causes, as a sudden twist of the limb in dancing, walking, leaping, or stepping into bed. When there is a faulty conformation of the knee-joint, attended with a relaxed state of the ligaments, it may take place spontaneously, from the action of the extensor muscles conjoined with slight rotation of the leg, the thigh being fixed in the straight position. Sometimes the displacement is occasioned by direct violence, forcing the bone towards the opposite side of the articulation, or twisting it upon its long axis. The accident is most common in young and middle-aged persons. Bryant records a case in a child ten months old.

The amount of injury sustained in these luxations by the ligaments of the knee is variable. When the displacement is partial, as it is in most cases, the probability is that the laceration is very slight, whereas in the more complete forms it must necessarily be proportionately extensive. In some instances the ligament of the patella is nearly torn across, and the lateral ligament is either very much stretched or ruptured.

Of the two lateral dislocations that *outwards*, fig. 684, is the more common, the patella lying at the external part of the joint, its outer edge being directed backwards, and the inner forwards. The signs are characteristic. There is a remarkable depression in front of the knee, with a corresponding prominence on the outside ; the inner condyle can be distinctly felt under

Fig. 684.   Fig. 685.

Dislocation of the Patella Outwards.   Dislocation of the Patella Inwards.

the skin, and the leg is in a painfully extended position, without the possibility of being flexed.

In the dislocation *inwards*, fig. 685, the situation of the patella is reversed, its inner border being turned backwards and the outer forwards. The leg is extended and cannot be bent, the outer condyle looks as if it were depressed, and a characteristic prominence exists at the internal aspect of the knee.

Restoration is effected by placing the patient upon his back, and flexing the thigh upon the pelvis, the lower part of the leg resting upon the surgeon's shoulder, as he sits upon the edge of the bed. The object of this procedure is to relax the knee as completely as possible, when, pressure being applied to the bone with the thumb and fingers, the patella will be drawn into its natural position by the action of the extensor muscles.

Although these dislocations are generally reduced with great facility by the method here advised, and very frequently even by the patient himself, cases occur in which the operation is extremely difficult, the most skilful surgeon being foiled for a long time, notwithstanding the best directed efforts. It is said that Sabatier was completely foiled in an instance of this kind; and Dorsey, on one occasion, nearly experienced a similar fate. Being called to a young lady who had luxated her patella in stepping into bed, he did not succeed in accomplishing his object until after many fruitless attempts, although he saw the patient within five minutes after the accident. When the obstacle is unusually great, it may generally be surmounted by forcibly flexing the leg, and then rapidly extending it; a procedure which has the effect of disengaging the bone from its impacted position. In the case of a boy, aged nine years, mentioned to me by Dr. John H. Packard, of this city, the dislocated bone slipped back into its natural position during the struggles consequent upon the administration of ether.

The dislocation in which the patella is displaced edgewise, *vertically*, or upon its long axis, is a very singular accident, the possibility of which was long denied by nearly all surgeons. It is, indeed, difficult to conceive how a bone, which is so firmly imbedded as this is in tendinous matter, can lend itself to such a freak, which has the effect of turning it completely on its side, so that its outer edge lies immediately under the integument in front of the knee, while the inner rests in the subcondyloid fossa of the femur, being firmly and almost immovably wedged in its new position, the anterior face looking inwards, and the posterior outwards. Sometimes the position of the patella is almost completely reversed, the surfaces changing situations, the anterior looking backwards, and the posterior in the opposite direction.

The accident is generally produced by violent muscular action conjoined with a sudden and forcible twist of the knee; or by a fall or blow upon the bone, at a moment when the leg is semiflexed and strongly rotated upon its axis. A case has been related in which it occurred in wrestling; and at least two instances are known where it resulted from the forcible collision of the knees in a sham fight on horseback. In a case reported by Professor Rochester, of Buffalo, the dislocation was caused by a fall, in which the patient, a youth of sixteen, struck the joint against a curbstone.

The signs are characteristic. The leg is perfectly straight, but may occasionally be slightly flexed, although not without excessive pain; the patella forms, by its outer edge, a hard, prominent ridge in front of the knee; a deep depression exists upon each condyle; and the extensor muscles are in a state of extreme tension.

The reduction is generally extremely difficult, owing to the trouble which is experienced in disengaging the bone from the subcondyloid fossa, where it is almost as firmly impacted as if it were screwed fast. On several occasions, indeed, the most violent efforts, conjoined with the division of the ligament of the patella, were insufficient to accomplish the object. In a case reported by Dr. Gazzam, of Pittsburgh, the only effect of the operation was to render the bone a little more movable, but the attempts to reduce it were as unavailing as before. In another instance, the surgeon, Dr. Wolff, divided the ligament below, and the extensor tendon above, the bone, and yet he found it impossible to effect restoration. Violent disease of the joint ensued, and the patient ultimately perished from profuse discharge and hectic irritation. Fortunately, such measures are not likely to be repeated, since experience has fully shown not only their utter inefficacy, but great danger. In these very rebellious cases, it is not impossible, as suggested by Professor Agnew, that the displaced bone, in addition to its strong impaction in the subcondyloid fossa, becomes engaged in a slit in the fibrous structures in which the patella is naturally imbedded, thus greatly augmenting the difficulty of the reposition.

The proper method of reduction consists in flexing the thigh strongly upon the pelvis, and in bending the leg forcibly, to the fullest extent, upon the thigh, the limb being again

immediately brought into a straight line, at the same time that an effort is made to push the bone strongly over towards the inner part of the joint. By repeating this manœuvre several times in rapid succession, the patella suddenly leaves the subcondyloid notch, and jumps back, with a distinct snap, into its natural situation. Extension, even when carried to excess, is of no avail in effecting reduction; on the contrary, in every case, except one, recently under the care of Dr. Coombs, in which it has been tried, it has signally failed, by causing, apparently, still further impaction of the bone.

After the reduction of these different dislocations, the patient must be subjected for some time to rest and the usual antiphlogistic measures; and when he is able to move about, the joint must be supported for many months with a gum-elastic cap.

Displacement of the patella *upwards* can only occur in connection with a rupture of the ligament of that bone, in consequence of the inordinate action of the extensor muscles, or violence applied to the anterior surface of the knee. The injury is easily recognized by the flattening of the joint, by the projection upon the inferior part of the thigh, and by the inability of the patient to extend the limb. The treatment is the same as in fracture of the patella.

A few instances of *congenital* luxation of the patella are upon record; some of them of an equivocal character, others well authenticated. The occurrence is very uncommon. Perhaps the most remarkable example of double congenital luxation of the patella is one related by Dr. Caswell, of Providence, in which this anomaly occurred in five members of one family, extending over three generations.

DISLOCATIONS OF THE KNEE.

Dislocation of the knee is of very infrequent occurrence, owing, mainly, to the numerous and powerful ligaments by which the articulating surfaces are united together. In this respect, there is no other joint in the whole body so well provided. If it were not for this arrangement, luxation could hardly fail to be very common, as the knee not only admits of extensive motion, but has unusually shallow surfaces, with no very strong support from the neighboring muscles, such, for instance, as exists in the hip, shoulder, and elbow.

The tibia may be thrown from the condyles of the femur in four different directions, forwards, backwards, inwards, and outwards, or to either side. The latter two are the most common, and are always incomplete, owing to the great extent of the articular surfaces, and the difficulty of rupturing all the ligaments in the lateral direction of the joint. The anterior and posterior dislocations are also for the most part partial. Besides these displacements, the knee is subject to a species of subluxation, dependent upon a change of location of the semilunar cartilages. This, indeed, is more common than all the other forms of the lesion together, and is, therefore, of sufficient importance to demand separate notice.

Fig. 686.

Dislocation of the Tibia Forwards.

1. Dislocation *forwards*, fig. 686, is occasioned by falls upon the foot while the knee is in a bent position, or by force acting upon the anterior and inferior part of the thigh, driving the femur backwards behind the head of the tibia; in either case, the occurrence will be promoted if, at the moment of the injury, the leg is slightly rotated upon its axis, so as to increase the strain upon the joint.

The head of the tibia is pushed upwards and forwards, lying in front of the condyles, and generally presenting a somewhat twisted arrangement; the patella is drawn up beyond its natural level, into a sort of hollow, just above the tibia, and may easily be lifted up with the thumb and fingers; the tendon of the extensor muscles is much relaxed; and there is shortening of the leg from an inch and a half to two inches. The condyles of the femur are situated in the ham, where they form a large tumor, which gives the part an unusually prominent appearance, and which occasionally exerts such a degree of compression upon the vessels as to interrupt the circulation in the dorsal artery of the foot.

The complete form of dislocation of the tibia, whether forwards or backwards, must necessarily be attended with most extensive rupture of the ligaments of the joint, and is,

therefore, always to be regarded as a very serious accident. When the condyles are impelled backwards with unusual violence, there will be great danger of laceration of the popliteal vessels, especially of the artery, either in the form of direct rupture, or of a partial destruction of its inner and middle tunics; occasioning, in the one case, copious subcutaneous hemorrhage, the pressure of which may finally cause gangrene of the limb; and, in the other, the gradual dilatation of the artery into an aneurismal tumor, the ultimate effects of which may not be less disastrous. In every instance there is rupture of the popliteal muscle. When the injury to the joint and the parts around is very grave, the danger to limb and life may be such as to require amputation; but, ordinarily, the patient rapidly recovers from the immediate effects of the lesion, and eventually obtains a useful limb, although it may remain weak for a long time.

The reduction is readily effected by counterextending the thigh and pulling the leg somewhat backwards, the surgeon's arm resting in the ham, and pressure being made upon the head of the tibia.

The following case, the only one that I have ever seen of dislocation of the head of the tibia forwards, affords a good illustration at once of the symptoms of the accident, and of the proper method of reduction.

A very large, stout, heavy woman, forty-eight years of age, received a severe fall from the sudden slip of the right foot, which, bending outwards, caused the whole weight of the body to be thrown upon the corresponding knee. I saw her four hours after the occurrence of the accident, when several fruitless attempts had already been made at reduction. The knee, which was very painful and a good deal swollen, appeared to be unusually wide from side to side; a circumstance partly due to the tumefaction of the soft parts. The leg was one inch and a half shorter than the opposite one, and in a straight line with the thigh. The patella had sunk behind the head of the tibia, into a kind of hollow, which imparted to the front of the joint a flattened aspect. Upon grasping the bone, however, with the thumb and fingers, it was easily drawn forwards, leaving a remarkable vacuity behind, in consequence of its distance from the inferior extremity of the femur. The condyles of the thigh-bone lay in the popliteal space, posterior to the head of the tibia, where they formed a large prominence, more distinct on the inside than on the outside, and situated, as it were, in the upper and back part of the leg, the muscles of which were unusually tense. The head of the tibia lay in front of the condyles, where its outline could easily be traced with the eye and finger. Above this bone, as already stated, was the patella with its ligament and the tendon of the extensor muscles, forming a broad, thick cord in front of the thigh-bone, from which it was removed more than two inches. The leg was easily drawn away from its fellow, but could not be carried inwards, showing that there was extensive rupture of the internal lateral ligament. There was no contusion of the soft parts, nor any discoloration of the integument.

Chloroform having been administered, a stout lac was applied to the upper part of the thigh, and confided to an assistant, to make the requisite counterextension, while extension was made by another assistant grasping the foot, the limb being in the extended position. Placing now my left forearm behind the knee, and requesting the aids to pull gently and steadily, I suddenly, with my right hand, bent the leg backwards, and thus in a few seconds effected the reduction, the bone returning with a distinct snap. The limb being laid in an easy position, cold cloths were applied to the knee, and half a grain of morphia administered to allay pain and prevent spasm.

No untoward symptoms appeared after the reduction. The patient kept her bed for nearly a fortnight, and made free use, after the first twenty-four hours, of medicated lotions, to moderate and subdue inflammation. Purgatives and light diet were also enjoined. In due time passive motion was instituted; the limb was frequently bandaged; and in less than a month from the time of the accident, the woman was able to walk about the house with the aid of crutches. The joint, however, remained weak for a long while, and even now, several years after the occurrence of the injury, the slightest fatigue is attended with temporary lameness.

2. Luxation of the tibia *backwards*, fig. 687, is so rare an accident that the possibility of its occurrence was called in question by many of the older surgeons. Modern experience, however, has not only shown the error of this opinion, but has pointed out with great accuracy the mechanism, signs, and method of reduction of the displacement. The causes are similar to those of luxation forwards.

The head of the tibia lies in the ham, where it compresses the popliteal vessels and nerves, pushes back the popliteal and other muscles, and forms a distinct prominence, easily perceptible by sight and touch. In front of the joint is the large projection repre-

senting the condyles of the femur, and immediately below it the patella, with a strongly marked depression on each side, its ligament being drawn tightly under the articular surface of the thigh-bone, and the tendon of the extensor muscles firmly stretched. The leg, which has the appearance of being slightly rotated, is always considerably shortened, although less than in the luxation forwards. In regard to its position no definite rule can be laid down, as it varies much in different cases, being at one time flexed, at another extended.

The reduction is effected upon the same principles as in the dislocation forwards, the thigh and leg being pulled in opposite directions, and pressure made upon the head of the tibia, while the patella is fixed by the hand in front.

3. The *lateral* dislocations of the tibia are always incomplete. They occur with nearly equal frequency, generally from falls, or from the passage of the wheel of a carriage, in which the femur is violently twisted while the leg itself is firmly fixed. Another cause is force applied to the lower and lateral part of the leg at a moment when the knee rests upon a hard, resisting object, and the trunk is inclined sideways, thus throwing the whole strain upon the edge of the joint. Much injury of the soft parts almost always attends these displacements, and the leg generally presents a remarkably twisted appearance.

Fig. 687.

Dislocation of the Tibia
Backwards.

In the luxation *inwards*, fig. 688, the head of the tibia is thrown off the corresponding condyle of the femur, and forms a large tumor at the inner side of the knee. In the displacement *outwards*, fig. 689, the signs are reversed, the tibia projecting at the external aspect of the joint, and the condyle at the inner. The leg, in both cases, is slightly flexed and rotated on its axis, the extensor muscles are relaxed, and a marked depression exists in the natural situation of the patella, which is pushed to one side or the other, according to the character of the displacement. The diagnostic signs are the twisted state of the limb, and the great increase of the width of the joint.

Owing to the extensive laceration of the ligaments of the joint, the lateral dislocations are reduced with great facility. All, in fact, that is necessary, is, while the thigh is fixed by an assistant, to pull the leg by grasping it just above the ankle, and to push the head of the tibia in a direction contrary to that of its displacement.

Fig. 688.   Fig. 689.

Dislocation of the Tibia   Dislocation of the Tibia
Inwards.   Outwards.

The after-treatment of all these luxations must be conducted upon strictly antiphlogistic principles. The patient should be confined to his bed for at least a month, and blood should be freely taken by leeches, and even by the lancet, if he is robust, or if the inflammation runs at all high. The great danger is ankylosis, which it will require the utmost care and diligence to prevent. The joint must be supported in an easy position, and passive motion must not be instituted too soon, lest it interfere with the reunion of the ruptured ligaments. When the patient is able to walk, the knee must be protected with a laced cap, and its tone improved by the cold douche, stimulating embrocations, and dry frictions.

Complicated dislocations of the knee are not of infrequent occurrence, and are always to be dreaded on account of the constitutional sympathies which they are sure to awake. When the joint is laid freely open, and the soft parts are otherwise seriously injured, there can hardly be any doubt as to the propriety of immediate amputation, for such cases nearly always terminate unfavorably, the patient dying either of tetanus, erysipelas, pyemia, traumatic fever, or excessive suppuration; or, if he chance to recover, he will owe his life to good luck rather than to the skilful management of his attendant. It is generally difficult to make the patient comprehend the importance of what will always appear to him so harsh

a measure, especially if he is a young man of temperate habits, and in excellent health at the time of the injury ; he will resist the operation in spite of the arguments and entreaties of his surgeon, and will only consent when it is too late to be of any benefit. I am satisfied that there is no class of lesions more dangerous to both limb and life than compound dislocations of the knee, especially when at all severe ; and I, therefore, do not hesitate to recommend the prompt adoption of decisive measures. When the soft parts are not too much affected, excision may occasionally be substituted for amputation, as in the cases reported by White and other surgeons, although, in general, the latter is unquestionably by far the safer procedure.

Dislocations of the knee are sometimes complicated with laceration of the popliteal vessels ; an occurrence in which the only resource is amputation of the thigh, performed without delay, immediately above the seat of the injury. Mr. George Lowe recently reported two cases in which this expedient was necessary.

Examples of *congenital* luxation of this joint have been reported by different authors, as Cruveilhier, Robert, Guérin, Kleeberg, and Bard. The displacement, which is generally incomplete, and associated with other malformations, may occur in any direction, but that forwards is by far the most common.

In 1863, Dr. Karsner sent to me at the College Clinic a female child, two years of age, on account of a congenital dislocation of each knee, accompanied by absence of the patella. The tibia lay in front of the femur, the situation of its head being indicated by a distinct prominence, and by a peculiar crescentic fold in the skin. The condyles of the thigh-bone, on the contrary, formed a very large tumor on the back part of the leg, and seemed to have been considerably rounded off. The leg was shortened about two inches and a half. The child, which was puny and unhealthy, could readily extend the limb, as well as move it laterally, but was unable to flex it at the joint, nor could this be done beyond a few inches by my own efforts. The dislocation was reduced by extension and counter-extension, but immediately recurred upon their cessation. In another case, in an infant four weeks of age, the articular extremities were in a direction precisely the reverse of the preceding, the head of the tibia being behind, and the condyles of the femur in front and internally. There was no patella on either side.

DISLOCATIONS OF THE SEMILUNAR CARTILAGES.

The semilunar cartilages are subject to a species of displacement known under the name of subluxation, an affection which was first described by Mr. Hey, of Leeds, and which is most commonly met with in feeble, delicate persons, the subjects of chronic disease of the knee. A sudden and forcible twist of the joint occasioned by striking the toes against a stone, or an accidental slip in walking while the foot is turned inwards and the thigh outwards, is the usual cause of the mishap. The lesion essentially consists in the partial removal of the semilunar cartilages from their natural position, thus allowing them to become wedged in between the tibia and femur, simply as an effect of the relaxed condition of their ligamentous connections. Occasionally, however, the wrench is so violent as to detach some of these connections from the bone.

Well-marked *symptoms* always attend this form of luxation. The patient is suddenly rendered conscious of some accident, which causes him to feel faint and sick, and immediately compels him to sit down. The pain is very excruciating, and he is unable to stand, or to extend the limb, which is generally semiflexed. If the joint be examined within a few minutes after the occurrence of the injury, its size and shape will be found to be perfectly natural, and an inexperienced surgeon might conclude that the case was merely a slight sprain. In a short time, however, considerable swelling sets in, and the articulation before long imparts a distinct sense of fluctuation from the deposit of synovial fluid, caused by inflammation of its lining membrane. The excessive pain and shock are due to the pressure which the tibia and femur exert upon the displaced cartilages, in consequence of the changes in their mutual relations, and, also, to the forcible distension of some of the ligamentous structures of the joint. The dislocation, having once taken place, is extremely liable to recur from the most trivial causes ; and under such circumstances I have repeatedly noticed that, although the patient was always obliged to keep his leg in a slightly bent position, yet he was able, when he sat on a high seat, to move it nearly as well as the sound one.

The *reduction* must be performed under an anæsthetic during recumbency, with the thigh strongly flexed upon the pelvis. The surgeon, placing his arm in the popliteal hollow, and grasping the limb just above the ankle, bends the knee suddenly and forcibly,

and then rapidly extends it, at the same time imparting a movement of rotation to the leg. By this triple manœuvre the pressure of the condyles is taken off the semilunar cartilages, and the parts are enabled to return to their natural situation. Sometimes the ingenuity of the patient enables him to effect reduction when that of the surgeon fails. Sir Astley Cooper mentions the case of a gentleman who was in the habit of relieving himself by bending the thigh inwards and pulling the foot outwards, as he sat upon the floor. In some instances, again, the parts return of their own accord after a failure of the usual means either during sleep, or while the patient is sitting up.

After such an occurrence the joint must be kept perfectly at rest until it has, in some degree, recovered its original tone, when the patient should wear an elastic knee-cap, and guard against any sudden twist of the limb, to prevent a recurrence of the dislocation. Sorbefacient liniments and the cold douche will be of service in promoting the removal of effused fluids, and imparting vigor to the relaxed structures.

DISLOCATIONS OF THE HIP-JOINT.

Dislocations of the ilio-femoral joint are far less frequent than those of the shoulder, a circumstance which evidently depends more upon the peculiarity of structure of these articulations than upon any difference in their motions, which are sufficiently free and varied in both, although certainly less so in the former than in the latter. The hip-joint affords the best type of the ball and socket joint in the body. The acetabulum is of immense depth, and, therefore, readily accommodates the large, well-formed hemispherical head of the femur. The glenoid cavity of the scapula, on the other hand, is very shallow, and yields very inadequate support to the head of the humerus, in the varied and extensive movements of the shoulder. Besides, there is a great difference in the ligaments which bind the bones to each other in these articulations. The capsular ligament of the shoulder is comparatively weak, while that of the hip is by far the most powerful in the body, at the same time that it is most closely and firmly fitted around the parts which it is designed to retain and to protect. In addition to this, the latter has a ligament peculiar to itself, the interarticular, which serves to connect the head of the bone directly to the margin of the acetabulum, an arrangement which is altogether wanting in the shoulder, the long head of the biceps forming a very imperfect substitute. Finally, the hip-joint is under the cover and protection of large and powerful muscles, which are much more capable of resisting the effects of dislocating agents than those of the shoulder, which, in fact, often rather promote the occurrence of the accident, if they do not actually produce it by their own ill-directed efforts.

Dislocations of the hip-joint are much less frequent in women than in men, simply because of the differences in their occupations. If women were as much exposed to all kinds of external violence, especially to falls and blows, as the other sex, they would, doubtless, suffer quite as often, not only from these accidents, but also from luxations of the other articulations. Displacements of the shoulder occur at least from six to eight times as frequently in the male as in the female, and in the hip-joint the disproportion is still more remarkable.

Displacement of this joint is, next to that of the shoulder, more frequent than in any other joint of the body. Of the cases collected by Malgaigne, 494 in all, 321 occurred in the shoulder and 34 in the hip, the clavicle coming next in order.

Age exerts an extraordinary influence upon the production of these accidents. It is very uncommon to meet with a luxation of the hip-joint in children, because a degree of force capable of inducing it in the adult would be more likely to lead to separation of the epiphyses of the bone, owing to its imperfect development, and consequent inability to resist external injury. In the old the lesion is also unusual, for at that period of life the osseous tissue is so brittle as to be liable to be broken by the slightest causes. Hence, fracture of the neck and upper extremity of the femur is much more frequent in both sexes after the age of fifty-five than displacement of the head of that bone from the acetabulum. Dislocation often occurs from the twentieth to the twenty-fifth year, but is most common from the thirtieth to the forty-fifth. The youngest case of displacement of the hip-joint of which I have any knowledge happened at six months; the oldest at eighty-six years.

The head of the femur is susceptible of being dislocated in four principal directions; upwards, upon the dorsal surface of the ilium; backwards, into the sciatic notch; downwards, into the thyroid foramen; and forwards, upon the pubic bone. Of these displacements, the first is by far the most common; next in order of frequency is that into the sciatic notch, and the rarest of all is the last. Sir Astley Cooper, whose experience in

dislocations of the hip-joint was very great, estimated that out of every twenty cases twelve would be on the dorsal surface of the ilium, five in the sciatic notch, two in the thyroid foramen, and one on the pubic bone. Of 104 cases, collected by Professor Hamilton, 55 were iliac, 28 sciatic, 13 thyroid, and 8 pubic. The observations of surgeons generally accord with the results of these statistics. To the extreme rarity of the last two forms of luxation every practitioner can bear testimony. The reason of the great frequency of iliac dislocations is to be found, I presume, rather in the position in which the thigh is usually placed at the moment of the accident than in any differences in the structures of the hip-joint at particular portions of its extent, certain attitudes of the limb always favoring the occurrence of certain displacements.

A simultaneous dislocation of both hip-joints is occasionally met with, as in an instance recorded by Professor William Gibson; but such an occurrence is exceedingly uncommon. The accident may be symmetrical, or the head of one bone may lie in one situation and that of the other in another. Thus, Cooper has recorded a case in which one displacement was iliac and the other thyroid. A similar example occurred to Dr. Boisnot, of this city, in a man, forty-two years of age, who was crushed by the fall of a heavy sack of wool in which one thigh-bone was luxated upon the iliac and the other upon the pubic bone. In a case of double dislocation witnessed by Dr. Packard, one bone rested on the ilium, and the other in the thyroid foramen. T. C. Barker has reported an instance of double thyroid, and H. L. Pritchard one of double iliac, displacement; Pollard, of iliac and thyroid; Crawford, of iliac and sciatic, and W. O. Roberts of thyroid and iliac. These accidents are generally occasioned by heavy pressure, blows, or falls, inflicted at a moment when the body is "doubled up," or compressed into a narrow space.

Besides these luxations, there are several others, which will be briefly noticed under another head, as rare, unusual, or anomalous dislocations of the hip-joint. It will greatly simplify the study of the four principal forms of this accident if they be described as the iliac, sciatic, thyroid, and pubic, terms which, as they are easily understood, cannot fail to convey a clear general idea of the locality of each displacement to which they refer.

All these luxations are complete, the head of the femur being forced entirely out of its socket. Great violence is necessary for their production, and they always take place so much the more easily in proportion as the force is diffused over a large surface. I am not acquainted with a solitary instance in which they were the direct and immediate result of muscular contraction, as occasionally happens in dislocations of the shoulder-joint. Such an event could only occur when there is previous disease of the articulation, destroying its ligamentous connections. In what is called a spontaneous luxation, of which a number of examples are upon record, the displacement is always partial, the head of the femur never completely forsaking the cotyloid cavity. The violence in these accidents may act either directly upon the hip, or indirectly through the knee or foot, and the nature of the displacement will depend upon the direction in which it is applied. Thus, luxation into the thyroid foramen can only be produced when the limb is powerfully abducted at the moment of the accident, and the occurrence will be promoted if the strain is increased by the person having a heavy weight upon his shoulder.

Abduction of the limb seems to be the position most favorable to the production of dislocations of the hip-joint. Mr. Henry Morris, of London, in 1877, published a highly valuable article on this subject in the Medico-Chirurgical Transactions, in which he has clearly shown that in abduction the head of the femur is more than half out of its socket, and that, while in this condition, all the strong portion of the capsule is relaxed, excepting during complete extension, when the innermost fibres of the ilio-femoral ligament are rendered tense. "In fact," he adds, "it may be said that there is a natural tendency for the head of the femur to be displaced during abduction of the thigh." In corroboration of this view, Mr Morris has adduced the results of fifteen experiments performed, under varying circumstances, upon the dead subject, as well as several clinical observations verified by dissections after death, all tending to confirm his statements. These conclusions are now generally accepted, and they must, it is obvious, exert an important influence upon the reduction of the dislocations of this articulation. It was known, long ago, that at least two dislocations of the hip-joint, namely, the thyroid and the pubic, were, as a rule, caused during the abduction of the thigh bone; but it remained for the London surgeon to point out the fact that the two posterior displacements are generally produced in a similar manner. In none of his experiments did the head of the bone escape through a "button-hole" opening at the lower posterior part of the capsule; instead of this it always tore up a large flap in that situation.

In every dislocation of the hip-joint there must necessarily be more or less extensive

injury of the soft parts. The capsular and interarticular ligaments are torn, and a similar fate is always experienced by the rotator muscles of the femur, as well as by the pectineus and quadratus. The gemellus also generally suffers. The two large gluteal muscles, however, and the psoas and iliac, which are attached to the small trochanter, usually escape, or are, at most, only put upon the stretch. Occasionally a small scale of bone is detached from the head of the femur at the insertion of the round ligament, and a fracture of the rim of the acetabulum is also a possible occurrence. In what are known as the regular, or more common, dislocations, the capsular ligament is always torn at its weaker parts, the stronger, or ileo-femoral portions, generally retaining their integrity. When the violence has been uncommonly severe, a considerable effusion of blood may be expected within and around the joint; and there will then also be likely to be more or less contusion of the integument and muscles, especially if the injury has been direct.

1. In the *iliac dislocation*, the head of the femur is thrown upwards and backwards upon the dorsal surface of the ilium, fig. 690, resting in the fossa of that bone, either under or upon the small gluteal muscle. In some cases, although rarely, it is thrust a good deal forwards instead of backwards.

The accident occasionally occurs very early in life. The youngest case on record is one of eighteen months, treated by Dr. Fanning, of Catskill. Kirby, Yandell, and Buchanan

Fig. 690. Fig. 691.
Dislocation on the Back of the Ilium.

met with it at three years; Image at three and a half; Litten at four; Travers at five; J. C. Warren at six; Sir Astley Cooper at seven. I have seen it at six and at fourteen years, in male patients sent to me, respectively, by Dr. Whiteside, of Haddington, and by Dr. Saulsbury, of Delaware. In 1876, a girl, seven years old, was brought to the College Clinic, who at the age of six months had dislocated the left hip-joint. All the symptoms existed in a characteristic degree.

The *symptoms* of the accident, fig. 691, are sufficiently obvious, rarely exhibiting any material variation. The hip is considerably deformed, being more salient than natural, the upper part of the thigh is unusually full, and the gluteo-femoral crease is on a plane higher than common. The great trochanter is carried upwards and inwards, in closer proximity with the anterior superior spinous process of the ilium, and is more conspicuous than in any other accident except coxalgia, in its advanced stages. The head of the bone may readily be felt in its new situation, particularly in thin, lean subjects, and on rotating the thigh it is found to roll about under the finger. The limb is from one and a half to two and a half inches shorter than in the normal state; the foot is strongly inclined inwards, the big toe pointing towards the opposite tarsus; the knee, as the patient stands, is a little above and somewhat in advance of the sound one, any attempt to turn it out proving impracticable, and causing severe pain; the thigh is slightly bent

upon the pelvis, and may with a little effort be carried across the sound one : the leg is flexed upon the thigh ; the heel is raised off the floor ; and the limb, firmly fixed in its constrained position, cannot be restored to its proper length without reducing the dislocation, nor can it be moved except a little inwards. When the patient is recumbent, the foot rests on the bed, but the knee is considerably raised, and all attempts to extend it are unavailing.

A few examples in which the limb in the dorsal luxation was everted and slightly abducted have been reported ; a condition due, as is supposed by Bigelow, to a rupture of the outer fibres of the ileo-femoral ligament. It is a singular fact that, when this lesion in this ligament exists, eversion and inversion may occasionally be produced at pleasure simply by rotating the affected limb.

The luxation is generally occasioned by falls upon the knee or foot while the thigh is strongly abducted and thrown forwards beyond the line of the body. In this way the head of the femur, being powerfully rotated inwards, is thrust forcibly upwards and backwards, tearing the capsular ligament in that direction, escaping from the acetabulum, and lodging in the lower part of the iliac fossa, under or upon the small gluteal muscle. The accident may also be produced by violence applied directly either to the hip or to the upper extremity of the femur, as by the fall of a heavy body, when the limbs are widely separated, and the trunk is inclined strongly forwards. The two obturator, geminal, quadrate, and pyriform muscles are greatly stretched, and sometimes even partially ruptured, while the psoas and iliac are relaxed, as are also the adductor, pectineal, and gluteal. The round ligament is, of course, torn. The powerful tension into which the external obturator muscle, a fleshy mass of large size and great strength, is thrown by the accident, is the immediate cause of the immobility of the limb, of the inversion of the foot and knee, and of the excessive pain which follows any attempt at rotation and abduction.

The *diagnosis* is deduced from the great prominence of the trochanter and its proximity to the anterior superior spinous process of the ilium ; the inverted and shortened state of the limb ; the fixed position of the head of the bone in its new situation ; and the impossibility of abducting and rotating the knee.

Fig. 692.
Intracapsular Fracture of the Thigh-bone.

The accident with which this luxation is most likely to be confounded is fracture of the neck of the femur, fig. 692, within the capsular ligament. In general, however, the diagnosis is established with great facility. All, in fact, that is necessary is to remember that, in fracture, the trochanter is drawn backwards and is less salient than usual ; that the foot is everted instead of being inverted, as in luxation ; that the limb may readily be restored to its proper length by extension, but immediately resumes its former position when the extension is discontinued ; and, finally, that, when the ends of the fragments are brought in contact with each other, crepitation may promptly be elicited by rotating the thigh. Moreover, the limb may be moved, although not without great suffering, in every direction, and not merely inwards and slightly upwards, as in dislocation. In impacted fracture, a very rare occurrence, the head of the bone may always be felt in its natural position.

Doubt in regard to the diagnosis occasionally arises from injury of the superior extremity of the femur, attended with fracture of the great trochanter, from the detached fragment being drawn upwards and backwards by the action of the muscles, into the fossa usually occupied by the head of the bone in luxation. The signs of distinction are, the mobility of the broken piece, the absence of inversion of the limb, and our ability to carry the thigh about in different directions, although not without severe pain.

Severe contusion of the great trochanter, unaccompanied by fracture of the bone, may occasion uncertainty in regard to the diagnosis. The accident is liable to be followed by great pain and swelling in the upper part of the thigh and groin, by inability of motion, and by complete eversion of the limb, which, at the same time, feels numb and heavy, and is often swollen throughout its entire length. The absence of shortening of the limb, and the facility with which the head of the bone moves in its socket, are the signs which serve to distinguish the lesion from dislocation.

The symptoms of iliac dislocation are sometimes painfully simulated by fracture of

the acetabulum, allowing the head of the femur to escape into the pelvis. Or, a portion of the margin of this cavity may be broken off, and the bone ascend into the iliac fossa. This distinction is based upon the existence of crepitation and the greater amount of injury sustained by the soft parts. When the cotyloid border is detached, the fact will be denoted by the incessant tendency to recurrence of the dislocation after reduction. If the femur has pierced the pelvis the limb will be materially shortened and in a constrained, almost fixed position.

The degree of shortening attending the iliac variety of displacement is best ascertained by extending a piece of tape, or a graduated measure, from the anterior superior spinous process of the ilium to the centre of the tuberosity of the internal condyle of the femur on each side. Or, instead of this, the tape may be carried along the middle line of the body, from the centre of the fourchette of the sternum to the sole of the foot, placed at a right angle with the leg. The difference in the result will indicate the extent of the defect. There is considerable variation in regard to the amount of shortening in different cases. On an average, it may be stated to range from two inches to two inches and a half; but occasionally it is as much as three inches and a half, and, on the other hand, as little as an inch and a half.

The limb in this variety of luxation, instead of being inverted, is occasionally everted; sometimes in a remarkable degree, and without any ascertainable cause. Dr. E. M. Moore, of Rochester, recently reported an example in which, during an attempt at reduction, the head of the bone was reversed, so that it pointed anteriorly on the dorsal aspect of the ilium, with the toes projecting outwards, the shortening amounting to over two inches. In cases of this kind the diagnosis must hinge mainly upon the absence of crepitation and the great rigidity of the affected limb from the impaction of the head of the thigh-bone. Shortening is usually a prominent symptom.

Writers in describing this form of luxation almost invariably assert that there is less prominence of the great trochanter than in the natural state, whereas a little reflection will serve to show that such an opinion is altogether untenable. To satisfy one's self upon this subject, it is only necessary to examine the position which the femur assumes in consequence of the dislocation. The whole limb being strongly rotated inwards, the trochanter, as it lies in its new situation just above the rim of the acetabulum, or partly above and partly below, is necessarily tilted up and brought forwards, so as to augment, in a very striking degree, its saliency beneath the integument and muscles of the gluteal region. An excellent idea of the changes produced in the projection of the trochanter may be formed by alternately inverting and everting the foot strongly in the ordinary standing attitude, so as to make, on the one hand, the big toe of the rotated limb point against the opposite tarsus, and, on the other, the heel against the hollow between the tendo Achillis and the inner malleolus. In the former position, the bony eminence will be remarkably prominent, jutting out as a rounded mass, whereas, in the latter, it will hardly be perceptible, or, at most, comparatively small. In displacement of the head of the bone upwards and backwards, the projection is abnormally distinct, and is, therefore, a sign of great diagnostic value.

2. The *sciatic dislocation* commonly results from falls or blows applied to the foot or knee while the body is strongly inclined forwards upon the thigh, or the thigh upwards upon the pelvis. In either case the head of the bone, breaking through the posterior and lower part of the capsular ligament, slips backwards from its socket, into the sciatic notch, fig. 693, resting upon the pyriform muscle, between the sciatic ligaments and the convex surface of the iliac bone. The capsular ligament is severed, and the psoas, iliac, and obturator muscles are put upon the stretch, and occasionally otherwise injured. In a case observed by Mr. Syme the head of the bone rested upon and compressed the sciatic nerve.

This dislocation in its *symptoms* bears so close a resemblance to the iliac that some writers are disposed to regard them merely as modifications of the same lesion, the one being an exaggerated form of the other. I have myself, however, always looked upon them as separate and distinct varieties. The adjoining sketch, fig. 694, conveys an excellent idea of the appearances presented by the injured limb, and a comparison between it and the preceding will serve to show that they differ from those of the iliac luxation only in being less marked. The limb is shortened from half an inch to an inch, and so firmly impacted in its new position that it is impossible to bend or rotate it; the great toe rests against the ball of the sound one; the knee is turned in and advanced over its fellow, but not so much as in the dislocation upwards; the trochanter, which is uncommonly prominent, is lower down than natural, and, consequently, farther off from the anterior superior spinous process of the ilium; and the head of the bone is so deeply buried

in the sciatic hollow as to render it very difficult to detect it, except in thin, emaciated persons; not unfrequently, however, if, indeed, not generally, it may be felt by the finger inserted into the rectum or the vagina.   Both the thigh and leg are slightly flexed.

Fig. 693.

Fig. 694.

Dislocation into the Sciatic Notch.

The characteristic signs of the dislocation are, the situation of the head of the bone behind the acetabulum, a short distance above the tuberosity of the ischium; the firm impaction of the thigh in its new locality; the unusual distance between the trochanter and the spine of the ilium; and the fact first pointed out in 1877 by Dr. Oscar H. Allis, of this city, and soon afterward by Professor Dawson, of Cincinnati, that, when the two limbs, fig. 695, are raised to a right angle with the recumbent trunk, the shortening of the affected one will be materially increased, being seldom less than two inches instead of six or eight lines, as when the limbs are extended.   Another mark of distinction is that, if the thigh be extended, the back immediately becomes arched, so as to leave a hollow or space between it and the bed, and conversely.

Fig. 695.

Showing the difference between the two limbs.

In a sciatic dislocation recently under my charge, in a thin man, twenty-eight years of age, the limb was nearly one inch shorter than the sound one, and strongly flexed at the knee.   When an attempt was made to bring the thigh and leg in a straight line, the man complained of severe pain, and immediately raised his loins in such a manner as to admit of the ready passage of the fist and arm underneath.   When the body was extended, the knee became immediately bent, as at the time of the accident.   The limb lay close by the side of its fellow, and could not be carried either backwards or outwards, but was easily flexed on the pelvis.   When the man stood up, he threw his body very much forward, and the limb hung close by the side of the other, the knee being far in advance of the sound one and crossed somewhat over it; the foot was almost parallel with the other, but the heel was raised from the floor nearly two inches.   Both in standing and lying, the trochanter was at least one inch farther off from the anterior superior spinous process of the ilium than the opposite one, besides being unusually prominent; and the head of the femur could be distinctly felt on the dorsal surface of the ilium, at the upper part of the sciatic notch, rolling under the finger when the limb was rotated upon its axis.

In a case of unreduced sciatic dislocation of the left side, of eight years' standing, in a man twenty-five years old, I found, upon dissection, great inversion of the knee and foot, shortening to the extent of nearly one inch and a half, and great wasting of the entire limb.   The external gluteal muscle was nearly normal, but the middle and internal were excessively atrophied, shortened, and fused together, their fibres being very pale, sparse, and partially transformed into fatty and fibrous tissue.   The pyriform, also much reduced in size, was stretched over the head of the femur, and inseparably blended with the inner and middle gluteal.   The geminal muscles and the tendon of the internal obturator were elongated, and twisted around the neck of the bone.   The quadratus was lengthened, but not otherwise perceptibly changed.   The great trochanter was three inches and a half from the anterior superior spinous process of the ilium and four inches and a half from the crest of that bone, its top being on a line perpendicular with it.   The head of the femur lay across the upper part of the sciatic notch, two inches from the tuberosity of the ischium, and a few lines from the posterior inferior spinous process of the ilium, its distance from the crest of that bone being two inches and three-quarters.   It was nearly completely divested of cartilage, very rough, and studded with numerous little bony eminences.   Surrounding it was a false capsule, varying in thickness from the fourth of a line to a line and a half, and composed principally of the remnants of the pyriform and the two small gluteal muscles; it was translucent at several places, rough on its inner surface, with here and there a serous, glistening point, and presented a large quantity of reddish, filamentous tissue, immediately below the head of the bone, to which and to its neck it was firmly adherent.   The ilium and the sciatic ligaments which accommodated the bone were sound, and it was evident, from the manner in which the parts had been impacted, that but little motion existed after the accident.   The acetabulum was nearly filled by a fibro-cartilaginous substance, its edges having been rounded off by absorption.   No trace could be discovered of the capsular and round ligaments.

3. In the *thyroid dislocation*, fig. 696, the head of the femur is thrown downwards and forwards into the thyroid foramen, resting upon the external obturator muscle, by which that opening is covered in, the great trochanter being turned backwards towards the acetabulum.   It is caused by falls upon the foot or knee while the thigh is widely separated

Fig. 696.   Fig. 697.

Dislocation into the Thyroid Foramen.

from its fellow, and inclined sharply backwards.   It may also be occasioned by a heavy body, such, for example, as a sack of corn, striking the hip while the limb is in a state of abduction, and the trunk bent forwards.   The gluteal muscles are drawn downwards, considerably flattened and put upon the stretch; the pyriform is elongated and tense; the

interarticular ligament and the lower portion of the capsular ligament are torn; and the extensor muscles of the thigh form a hard, firm mass, reaching from the pubic bone to within a short distance of the knee.

The thyroid dislocation occasionally occurs at a very early age, as in a case recorded by Powdrell, in a child six months old. Bigelow met with one at the age of two years, and several other examples of a similar kind are to be found in the annals of surgery.

The *symptoms*, as seen in fig. 697, are remarkably prominent and distinctive. The hip is deprived of its convexity, and in place of the projection formed by the trochanter there is a decided flattening, and sometimes even a positive depression; the trochanter, moreover, is removed considerably farther from the anterior superior spinous process than in the natural state. The limb is increased in length from an inch and a half to two inches, and, owing to the tension of the gluteal muscles, stands off in an awkward and constrained manner from the sound one, the knees being in consequence widely apart from each other. The trunk is bent forwards by the action of the psoas and iliac muscles, which are greatly stretched; and a large tumor is perceptible in the region of the thyroid notch, caused by the presence of the head of the femur, which, however, can only be felt distinctly in thin subjects, and in the absence of swelling. The knee is extended and lower than the sound one, and the foot, usually a little everted, is widely separated from its fellow. The movements of adduction, extension, and rotation are impracticable, but those of abduction and flexion may be executed by the surgeon, although not without excessive suffering. In many cases the head of the displaced bone may be distinctly perceived by the finger introduced into the rectum or the vagina.

When the patient stands erect and is viewed in profile, the body and limbs are found to form an obtuse angle with each other, owing to the contraction of the gluteal muscles, on the one hand, and to that of the iliac and psoas, on the other, the latter presenting at the same time a tense ridge at the side of the thigh, perceptible both by sight and touch; the toes rest on the floor while the heel is usually somewhat elevated; the hip, by its flattened condition, contrasts strikingly with its fellow; the femoro-gluteal crease is lower than natural; and the knee is greatly in advance of the opposite one. If the body be extended so as to bring it on a line with the thighs, the effort will not only fail, but cause severe pain.

The diagnosis is based upon the widely separated state of the knees, the elongation of the limb, which does not exist in any of the other luxations of the hip, the forward inclination of the body, the flattened state of the buttock, the excessive tension of the iliac and psoas muscles readily felt by the finger, and the impossibility of adducting, extending, and rotating the leg. Another valuable sign is afforded by the great trochanter, which will be found to be farther off from the anterior superior spinous process of the ilium than its fellow on the opposite side.

4. The *pubic dislocation* is so uncommon that it may very properly be classed among the rare forms of the accident. As the name implies, the head of the femur lies upon the horizontal branch of the pubic bone, or, rather, upon this bone and the iliac, fig. 698, above Poupart's ligament, and between the anterior inferior spinous process of the ilium and the femoral vessels, under cover of the iliac, psoas, and straight muscles. The displacement is caused by falls while the limb is pushed backwards and outwards, and there is a heavy load upon the shoulder, as when a man carries a bag of wheat, and his feet suddenly give way under him. Another mode in which it may be produced is by the sudden bending of the body backwards while the foot is implanted in a ditch or hollow and the femur is kept straight by the action of its extensor muscles. Under these circumstances the head of the bone ruptures the upper and inner portion of the capsular ligament, and slips out of its socket into the groin. Mr. Ure, of London, has reported a case in which the dislocation was caused by inordinate muscular contraction in the act of "striking out," as it is termed, in swimming. The man, who felt a peculiar catch in the right groin, which he attributed to cramp, was able to walk, although not without considerable difficulty, after the accident, and the reduction was readily effected by manipulation.

In this luxation, fig. 699, the limb is from half an inch to an inch shorter than the other; the foot and knee are everted, and separated from their fellows, although in a less degree than in the thyroid displacement; the buttock is flattened; the great trochanter lies nearer the middle line than naturally; the femoro-gluteal fold is above its ordinary level; and a distinct prominence, hard, rounded, and easily impressed by moving the leg, exists in the groin, just above Poupart's ligament, representing the head of the femur. Adduction and rotation inwards are impracticable owing to the contraction of the external rotator muscles and the tension of the anterior branch of the ilio-femoral ligament. In a case of

pubic dislocation seen by Physick, in 1805, the head of the bone lay below Poupart's ligament, directly before the acetabulum, the foot and knee were everted, and the limb was a very little longer than the sound one. Larrey has recorded an instance in which the femur projected nearly at a right angle with the body. Sometimes the anterior femoral nerve is pressed upon, causing pain and a sense of numbness along the whole length of the thigh.

Fig. 698.   Fig. 699.

Dislocation on the Pubes.

The flattening of the buttock, the slight shortening of the limb, the eversion of the toes, the impossibility of rotating the thigh inwards, and the existence of the head of the bone in the groin, are marks which sufficiently characterize the accident to prevent mistake.

This luxation is sometimes witnessed at an early age. Erichsen has recorded an instance in a child eighteen months old.

General Diagnosis.—Error of diagnosis in dislocations of the hip-joint can only be avoided by the most careful and thorough examination of the patient, not only once, but, if necessary, repeatedly. It will be well always, in the first instance, to make the patient, properly stripped, stand up, in order to observe what posture he assumes, and what control, if any, he may have over the injured limb. After this has been done, he should be fully anæsthetized, and examined as he lies successively upon his back, his side, and his abdomen, the limb being moved, if possible, in different directions, and measured with a graduated tape to ascertain whether there is any change in its length.

Upon comparing the four varieties of luxations above described with each other, it will be found that, with the exception of the first two, there are sufficiently broad marks of dissimilarity to render the diagnosis, with a little care, very easy. The thyroid is the only one in which there is any lengthening of the limb; in all the others it is shortened, least in the pubic, and most in the iliac. In the iliac and sciatic, the hip is abnormally prominent; in the other two it is flattened; in the former the knee and foot are inverted, in the latter they are everted, decidedly in the pubic variety, and generally very slightly in the thyroid. In all the head of the bone may generally, with a little care and patience, be perceived by the touch in its abnormal position, especially in thin persons, and before the occurrence of much swelling, rolling about when the leg is rotated upon its axis. The great points to be attended to, when there is any doubt in the diagnosis, are, the state of the limb as to the change in its length, axis, and movements; the position of the great trochanter, especially its distance from the anterior superior spinous process of the ilium; and the location of the head of the bone and our ability or inability to feel it in its new

situation. All that is necessary is to give proper heed to these considerations, and any uncertainty that may exist as to the true character of the injury will soon vanish. The investigation will, of course, always be materially facilitated by the use of an anaesthetic.

In the two backward dislocations a satisfactory method of determining the existence or non-existence of the injury consists, as originally suggested by Nélaton, in extending a line from the anterior superior spinous process of the ilium to the most prominent part of the tuberosity of the ischium. This line bisects the acetabulum, dividing it into two equal parts, and at the same time touches the summit of the great trochanter, the thigh being previously flexed at a right angle with the pelvis. If, therefore, the trochanter in any case, projects in a marked degree above this line the fact furnishes conclusive evidence, in the absence of fracture of the neck of the femur, of displacement of the head of the bone. In the sciatic luxation the difference in the length of the thighs, raised at a right angle with the pelvis, affords important information, and is a mode of examination which should never be omitted. The everted position of the limb in the pubic dislocation is, of itself, conclusive evidence of the nature of the case, as the elongation of the limb is in the thyroid. The diagnosis between fractures of the superior extremity of the thigh-bone and dislocations of the hip-joint is pointed out at sufficient length under the head of the dorsal or iliac form of the displacement.

When all the ordinary means, such as the most thorough and patient examination with the touch, sight, and mensuration, fail, the mystery may often be solved with an exploring instrument, inserted at various points of the hip, and moved about in different directions in search of osseous prominences and depressions. A long, slender needle, sinking in to a great depth in the natural situation of the acetabulum, would infallibly declare the absence of the head of the thigh-bone, as the existence of an unusual osseous tumor outside of that cavity would certainly indicate the location of that bone in its new position. As there are no important vessels or nerves in and about the hip, such a procedure would be entirely free from the danger of hemorrhage and even pain. My opinion, however, is that, although perfectly safe and easy, it will rarely be necessary in any case, the nature of the lesion being generally too well marked to elude detection.

Reduction by Manipulation.—The method of reducing luxations of the hip-joint by simple manipulation was occasionally pursued by some of the older surgeons, and it is even dimly shadowed forth in the writings of Hippocrates and Paulus Ægineta; it was distinctly recognized by Wiseman, in the seventeenth century, and successfully practised in the eighteenth by Pouteau, Turner, Anderson, and others; Physick employed it in a case of pubic dislocation, in 1811; its feasibility was taught, for many years, by Professor Nathan Smith, of New Haven, in his annual courses of lectures; and in 1835 special attention was directed to it by Deprès of Paris.

Modern experience satisfactorily shows that all the different dislocations of the hip-joint may, at least in their recent state, be reduced by simple manipulation, not unfrequently even without the aid of anaesthetics. For the full development of our knowledge of this fact we are indebted mainly to Dr. W. W. Reid, of Rochester, through whose agency the operation was first brought into general notice. In a paper, published in 1857, he clearly proved, by a series of well-executed experiments, dissections, and clinical observations, that replacement may nearly always be safely, certainly, and expeditiously effected without any assistants, pulleys, or, in short, any extraneous aid whatever. He erred, however, in supposing that the chief obstacle to restoration was the contraction of the muscles around the hip-joint, more especially those that are put upon the stretch by the malposition of the luxated bone. It remained for Professor Gunn, of Chicago, and Professor Moore, of Rochester, to show that the resistance is due, in great measure, if not exclusively, to the manner in which the untorn portion of the capsular ligament girds the head and neck of the femur; for, whenever this structure was thoroughly divided upon the dead subject, the reduction was generally very easily effected. In the iliac and sciatic forms of the accident an additional obstacle is occasionally presented by the pressure exerted by the iliac portion of the fascia lata upon the great trochanter when the limb is in this unnatural position.

Professor Henry J. Bigelow, in an exhaustive monograph on the "Mechanism of Dislocation and Fracture of the Hip," published in 1869, ascribes the difficulty of reduction exclusively to the resistance offered by the ilio-femoral, or, as he terms it, the Y ligament, which, as is now well known, always remains intact in the regular luxations of this articulation, whereas in the irregular or anomalous, as they are denominated, it is always torn. A similar opinion was enunciated by Von Pitha, of Vienna, in 1865.

The ilio-femoral ligament, hitherto regarded by most anatomists simply as an accessory

ligament to the capsular, or, indeed, as an essential portion of it, is attached, on the one hand, to the anterior inferior spinous process of the ilium, and, on the other, to the anterior intertrochanteric ridge by two fan-like slips, its general outline thus closely resembling the letter Y. Its width, at its origin, is only about half an inch, whereas below it is more than four times that extent. It is remarkably tough and strong, nearly three lines thick at its greatest point of development, and capable, as Bigelow has shown, of resisting a weight of two hundred and fifty to seven hundred and fifty pounds. The annexed sketch, fig. 700, affords a graphic illustration of the form, situation, and attachments of the ligament, as delineated in the work above mentioned.

Fig. 700.

Ilio-femoral Ligament.

The process of reduction consists of certain stages and evolutions, in which the shaft of the femur is employed as a lever, and the pelvis as a fulcrum, the object being, in the first instance, to dislodge the bone from its new situation, and then to induce the muscles to assist in drawing it into place, compelling it thus, as it were, to retrace its steps along the route travelled in the dislocation. In conducting the operation, the best plan is to make the patient lie upon the floor, as this affords a much firmer base of resistance than a lounge, bed, or table, and likewise gives the surgeon an opportunity of placing himself in any position that may be deemed advisable. Complete anæsthesia should be induced; and, if the patient be unusually stout and plethoric, blood may advantageously be taken from the arm, as a preliminary measure, although this will seldom be required. In the female, exposure of the person is avoided by means of a sheet. Everything being ready, the surgeon, grasping the knee with one hand, and the leg immediately above the ankle with the other, flexes the thigh upon the pelvis and the leg upon the thigh, such a step being absolutely necessary to relax the capsular and iliofemoral ligaments. The thigh, in the iliac displacement, is carried across its fellow at the union of its middle and upper third, and then simply rotated outwards. In the sciatic variety, the reduction is effected in a similar manner, with this difference, that the limb is lifted, as a preliminary step, high up across the opposite groin. In the thyroid luxation, the thigh, raised to a right angle with the pelvis, is, at first, abducted, and then strongly rotated inwards. In the pubic form of the accident, the thigh, after being elevated in the usual manner, is, in the first instance, abducted and drawn downwards, and then rotated inwards. In the "everted iliac" dislocation, the limb, as a preliminary step, is placed by flexion and rotation inwards in the position which it assumes in the ordinary form of the accident, when the reduction is effected in the usual manner, aided, if necessary, by adduction.

Mr. Morris, in the posterior luxations, effects reduction, after flexing the thigh, by rotating and circumducting the limb outwards; and in the anterior, after flexing the thigh, by abducting slightly and strongly circumducting and rotating inwards. In other words, in each set of cases, reduction, says Morris, "is effected, after first abducting the thigh, by rotating the head of the femur in the opposite direction to that in which it was rotated during dislocation, and in all cases the leg is flexed to relax the hamstring muscles and the sciatic nerve. In this way the head of the bone is brought below the acetabulum and rotated back again into that cavity, not simply on the side where the acetabular margin is less prominent, but where, also, a passage exists through the capsular ligament." The rim of the acetabulum does not often, Morris thinks, offer any actual resistance to reduction; but he considers it important to lift the head of the femur away from the innominate bone during flexion and abduction, in order the more readily to disengage that prominence from the sciatic nerve which is not unfrequently partially twisted around it.

Professor Bigelow, after having thoroughly relaxed the ilio-femoral ligament, the chief point of resistance in these luxations, by flexion of the thigh and leg, employs either rotation or vertical traction, the direction of the movement being regulated by the form of

the displacement. If the opening in the capsular ligament is too small to admit of easy reduction, it may readily be enlarged, as a preliminary measure, by circumducting the limb in a direction opposite to that in which it is designed to carry the head of the bone. For making vertical extension, which affords the most complete relaxation of the ilio-femoral ligament, Bigelow employs the tri-

Fig. 701.

Bigelow's Tripod for Vertical Extension.

pod, represented in fig. 701, the pelvis being secured to the floor by a padded band. Rotation may be effected by means of the transverse rod above the knee, while the head of the femur is carried from the dorsum of the ilium or the pubes in the direction of the tuberosity of the ischium by vertically raising the longitudinal rod attached to the calf of the leg. Such a contrivance is, of course, only adapted to hospital practice.

In old dislocations, additional obstacles to reduction exist, depending upon the rigid and contracted condition of the muscles of the hip and the adhesions formed by the plasma effused in consequence of the injury sustained by the affected structures. The period at which these impediments attain their full force must, of course, vary in different cases and under different circumstances. In an iliac luxation of one month's duration, under my charge, in 1855, in a very stout, muscular young man, I promptly succeeded in effecting replacement by simple manipulation, after complete failure with the pulleys employed for nearly an hour and a half, the patient being all the while thoroughly relaxed by chloroform. In 1863, at the College Clinic, I was equally fortunate, in a similar dislocation of twenty-seven days' standing, in a lad fourteen years of age. Successful examples of much longer duration have occurred in the hands of other surgeons.

In the pubic and thyroid dislocations, reduction has occasionally been effected by the heel in the perineum, the patient and surgeon lying in opposite directions, as in luxations of the shoulder. The pelvis being thus firmly fixed by the foot, extension is made by grasping the leg above the ankle, the limb being gradually carried over the sound one as the head of the bone approaches the cotyloid cavity. Or, instead of this, the leg may be flexed at a right angle with the knee, and a long, stout noose secured around the lower part of the thigh, and thrown over the operator's neck and shoulder, which will thus afford him much greater control over the limb. This method, however, which recommends itself by its simplicity, is chiefly applicable to very thin, feeble subjects, offering but little muscular and ligamentous resistance.

The late Dr. Brainard, of Chicago, in four cases of thyroid dislocation, promptly succeeded in effecting reduction by placing a piece of well-padded wood, four inches and a half in diameter, as a fulcrum, in the perineum, between the thighs, which were then used as levers, the limbs being extended during the operation, and the affected one carried slightly across the sound one. Occasionally a bedpost has been used for a similar purpose; but, in employing such an expedient, care must be taken not to raise the leg, otherwise the head of the femur may be thrown into the sciatic notch.

An old pupil of mine, Dr. George Sutton, of Indiana, has succeeded in reducing five cases of luxation of the thigh at the hip, four iliac and one sciatic, by placing a cloth cylinder, three inches in diameter, and from twelve to fifteen inches in length as a fulcrum, in the groin, and using the leg as a lever to lift the head of the bone over the rim of the acetabulum. The plan, it will be perceived, is similar to that adopted by some surgeons in reducing dislocations of the shoulder-joint.

Reduction with the Pulleys.— When manipulation fails, as it occasionally will, especially in very stout, robust persons, and in chronic cases, recourse must be had to the pulleys, for then even severe measures would be preferable to leaving the luxation unreduced.

and letting the patient remain a cripple for life. The general principles which should guide the practitioner in the use of these instruments have already been pointed out. I shall, therefore, limit myself here to a brief description of the operation as applicable to the several varieties of dislocations of the hip, premising that the employment of the pulleys, is, at best, an expedient of doubtful efficacy, often productive of much greater harm than benefit.

The patient should be laid upon his back on the floor, or on a firm table, lounge, or bed, between two strong objects, from ten to twelve feet apart, in each of which a large hook is fixed. A stout, soft piece of muslin, neatly folded, and at least four yards in length, is placed in the perineum, and being carried over the groin and buttock, its ends are tied together, and fastened to the hook behind the patient's head. Another band is carried around the upper part of the pelvis, and given to an assistant, to prevent the injured hip from being drawn down during the operation. Finally, a large wet towel is rolled around the lower part of the thigh, and over this is buckled a leather band with two lateral straps, each provided with a ring. Or, instead of the band, a stout fillet is employed, being fastened by means of a wet roller, or the French knot, the ends being so disposed as to come down on each side of the knee, a little below which they are to be tied. Best of all for this purpose is the contrivance delineated at p. 1111. The knee being now bent nearly at a right angle, and inclined a little across its fellow, the pulleys, secured to the extending band and the staple, are put in motion by gently drawing the cord. As soon as the apparatus is thoroughly put upon the stretch, and the patient begins to evince symptoms of suffering, as he will be sure to do if he has not taken an anæsthetic, the efforts are to be relaxed, to allow the muscles a little rest. After having waited a few minutes, the cord is again tightened, to increase the tension somewhat, when the efforts are to be again intermitted. Taking care to proceed in this slow, gentle, and gradual manner, until the head of the femur has reached the edge of the acetabulum, the surgeon intrusts the management of the cord to an assistant, while he himself, grasping the upper part of the leg, rotates the limb in a direction contrary to that of its displacement, and thus promotes the return of the bone to its socket, the reduction being generally indicated by a distinct snap. When the head of the bone hitches against the rim of the acetabulum, its disengagement may be materially facilitated by means of a fillet placed around the groin, and thrown over the operator's neck and shoulder, so as to enable him to lift the bone up to a level with the cotyloid cavity, into which it will then be drawn by the contraction of the muscles. The length of time during which the action of the pulleys is maintained must depend upon circumstances, the restoration, in some cases, being effected in a few minutes, in others not under several hours, if at all.

The annexed cut, fig. 702, illustrates the position of the patient during the operation, the arrangement of the pulleys and the extending bands, and the position of the limb.

Fig. 702.

Reduction of the Iliac Dislocation with the Pulleys.

In the iliac and sciatic dislocations the rule is to let the patient lie on his back, and after the extension and counterextension have been kept up for some time, to carry the affected limb across the opposite one, as this enables the head of the bone the more easily to disengage itself from the brim of the pelvis. In the thyroid and pubic varieties the extension is directed downwards and backwards, the foot of the affected limb being carried behind the sound one, and the patient lying upon the uninjured side. The manner of conducting the proceeding is represented in figs. 703 and 704.

Fig. 703.
Reduction of the Thyroid Dislocation.

In the attempts at reduction, the head of the bone, instead of returning to its socket in the act of being lifted out of its abnormal position, occasionally drops into some other, from which it may, perhaps, be more difficult to dislodge it than it was in the first instance. This accident is most liable to occur in the iliac luxation, which, as the head of the femur is moved about to disengage it from the iliac fossa, is readily converted into the sciatic. In a case reported by Dr. F. D. Lente, the head of the bone was thrown from the sciatic notch upwards under the anterior superior spinous process of the ilium. Occasionally the pubic displacement is changed into the thyroid; and an instance happened at the Pennsylvania Hospital, in the service of Dr. Neill, in which, during the reduction, the bone was thrown out of the thyroid foramen into the sciatic notch, from which it was afterwards returned with great difficulty by means of the pulleys. These accidents are generally unavoidable; but a knowledge of the possibility of their occurrence should put the surgeon upon his guard, that he may not be deceived under an idea that he has effected reduction when he has only succeeded in producing another displacement.

When the head of the bone has resumed its original position, as may always be known by the disappearance of the symptoms, and by a comparison of the limb with its fellow, a return of the accident is to be prevented by the observance of recumbency for at least three weeks, and by keeping the thighs close together by means of a bandage applied just above the knees during nearly the whole of this period. During the first eight or ten days the hip should be constantly covered with cloths wrung out of a strong solution of acetate of lead and laudanum. If the inflammation run high, leeches,

Reduction of the Pubic Dislocation.

active purgation, antimonial and saline preparations, and even general bleeding, may be demanded. After the morbid action has measurably subsided, sorbefacient lotions, and passive motion of the joint will be required, to promote the removal of plastic matter, and to prevent ankylosis.

It is seldom that any of the luxations of the hip recur after the bone has been properly replaced, for such are the depth of the acetabulum and the nice adaptation of the head of the femur as to render an event of this kind extremely difficult after recovery from the immediate effects of the injury. A remarkable instance, however, occasionally occurs, in which the same displacement happens again and again, in more or less rapid succession, in the same person. Thus, Mr. John F. South gives the case of a woman, who, in thirteen years, dislocated her femur upwards and backwards upon the ilium not less than twenty-one times; latterly from so trivial a cause as stooping, or turning in bed. The

accident originally happened when she was twenty-four years old, from slipping on a piece of orange peel. In this case the frequent recurrence of the displacement was doubtless due to extensive rupture of the ligaments of the joint; but now and then it is found to depend upon fracture of the border of the cotyloid cavity. However induced, the accident is always to be deplored, because it is generally irremediable.

Cases occasionally occur in which these dislocations are complicated with fracture of the superior extremity of the femur, rendering it extremely difficult, if not impossible, to effect reduction by any means that can be adopted. In such circumstances the most plausible plan would seem to be to attend to the fracture first, and after that has become consolidated, to attempt the restoration of the displaced bone in the usual manner. In some instances in which this practice was pursued the result was all that could be desired.

ANOMALOUS DISLOCATIONS OF THE HIP-JOINT.

The hip, like the shoulder, is subject to certain forms of displacement, to which, from the infrequency of their occurrence, the term rare, irregular, or anomalous may be applied. They are perhaps, for the most part, merely exaggerated states of the more ordinary varieties of the accident produced, as Professor Bigelow has shown, by the rupture of the ilio-femoral ligament. The annexed account comprises a succinct outline of the principal reported cases. In a majority of these the head of the femur was thrown downwards against some portion of the ischium; in one it was lodged in the perineum, and in one it was pushed upwards and inwards against the ilium, lying in the space between the two anterior spinous processes.

α. Mr. Robert Keate observed a case in which the head of the bone lay close to, and on a level with, the tuberosity of the *ischium*, where it could be distinctly felt rolling under the finger on moving the thigh, which was more than three inches longer than natural, much flexed upon the pelvis, and widely separated from the sound one. The leg was greatly bent, the foot much everted, and the large trochanter extremely sunk. By drawing the upper part of the femur outwards, and pressing the knee sharply inwards, the head of the bone returned to its proper place with a decided snap. Immediately afterwards, however, the limb could be elongated by slight traction, inducing the belief that a portion of the cartilaginous rim of the acetabulum had been broken off in the accident, which had been caused by the man falling from his horse into a deep, narrow ditch, the animal tumbling backwards upon him.

β. In a case described by Mr. Wormald, the head of the femur rested upon the upper part of the *tuberosity* of the ischium, above the quadratus muscle. The accident, caused by a leap from a third-story window, was attended with other injury, which soon proved fatal. The head of the bone was easily recognized in its new situation. The limb, considerably shortened and inverted, formed half a right angle with the body, and the shaft of the femur, crossing the pubic symphysis, was immovably fixed in this position.

γ. Mr. Earle and Mr. Adams have each recorded an example in which the head of the bone lay upon the *spine* of the ischium. In the former the limb was lengthened about half an inch, but there was neither eversion nor inversion; the trochanter was farther back and less prominent than natural; an extraordinary vacuity existed in front of the hip; and the outline of the sartorius and tensor muscles was uncommonly distinct, their edges being tense and almost sharp. In Mr. Adams's case the limb was inverted, and could not be rotated outwards when the knee was extended, nor abducted when the knee was flexed. Slight shortening existed.

δ. Dr. Kirkbride met with an instance in which the head of the femur was thrown upon the posterior part of the *body* of the ischium, between the tuberosity and the spine. The thigh lay across the sound one, the leg was flexed, the limb was lengthened at least an inch, and the interval between the great trochanter and the anterior superior spinous process of the ilium was much increased. Rotation was difficult, and extension impossible. The head of the bone was easily felt. The accident was caused by a fall from a considerable height, in which the body was crushed by a heavy piece of timber. The reduction was effected by the pulleys, but not without difficulty, for the man was very muscular, and the bone was firmly impacted in its new situation.

ε. In two cases seen by Dr. J. M. Warren the head of the bone rested against the ascending *ramus* of the ischium, the thigh projecting out laterally at a right angle with the trunk. A deep hollow existed at the spot naturally occupied by the great trochanter. The reduction was effected, in one of the cases, by manipulation; in the other, by the pulleys.

ζ. Dr. Willard Parker has reported a case of dislocation of the femur into the *perineum*, in a man, thirty-five years of age, who was injured by the fall off a boat, his body being at the moment bent strongly forwards and his feet separated. The limb projected at a right angle with the trunk, the buttock being flattened, and the toes turned slightly inwards; and the head of the bone, upon rotating the thigh, could be distinctly felt in the perineum behind the scrotum, near the bulb of the urethra. The reduction was readily effected by confining the pelvis and extending downwards and outwards, aided by moderate rotation. In this way the head of the bone was made to ascend over the ramus of the pubes into the thyroid foramen, from which it was afterwards conducted into the acetabulum by carrying the limb across the sound one.

η. A case similar to the above occurred to the late Dr. Charles Pope, of St. Louis, in a man, forty years of age, who had his body crushed by the caving in of a bank of earth, as he was standing in a bent position, with his limbs widely separated. The thigh, inclined somewhat forwards, formed a right angle with the body, and the head of the bone lay under the skin of the raphe of the perineum. The accident was associated with fracture of the leg and arm. Reduction was effected with the pulleys, the bone returning with a loud snap.

θ. Several cases have been observed in which the head of the femur was dislocated upwards and inwards into the space between the two anterior *spinous processes*. In one, examined by Mr. Morgan, the bone, lying in this precise spot, could be distinctly felt under Poupart's ligament, upon the brim of the pelvis. The prominence of the great trochanter was entirely lost, the thigh was shortened at least two inches, the toes were excessively everted, and the injured limb had a tendency to cross the sound one. Rotation was impossible, but all the other motions could be performed, although only in a limited degree, and not without great pain. Reduction was easily effected. A similar case has been described by Mr. Travers, caused by a fall, from a height of twenty feet, in which the left buttock struck upon a coil of chain cable. Here, however, the neck, and not the head of the bone, lay between the two anterior spinous processes, the head not being perceptible. The left buttock was flattened, and the limb, shortened and everted, had the appearance, when the patient stood erect, of being suspended from the anterior and lateral part of the ilium. A little below and to the outer side of this point was the great trochanter, easily distinguishable by the finger.

ι. In a case described by Mr. Luke, the head of the bone was lodged midway between the thyroid foramen and the sciatic notch, immediately beneath the lower border of the acetabulum. The limb was lengthened one inch, without eversion or inversion, and the head of the bone was easily felt in its new position. The reduction was accomplished without difficulty. The man dying from the effects of other injuries, the dislocation was reproduced in the dissection of the joint. The inferior gemellus and square femoral muscles had been torn, the lower part of the capsular ligament had given way, and the round ligament was completely detached. The patient, a stout man, fifty years of age, had been hurt by a fall into a dry-dock.

κ. Finally, Dr. W. E. Hodder, of Toronto, has recorded the case of a man, twenty-two years of age, in which the head of the femur was thrown under the *arch of the pubes*, by a large quantity of earth falling upon the loins and hips. The bone could easily be distinguished in its abnormal position, and the thigh, as the patient stood up, formed nearly a right angle with the trunk. The knee was everted, a remarkable concavity existed upon the dorsum of the ilium, the psoas and iliac muscles were very tense, and the great trochanter could scarcely be felt. The affected limb was, if anything, a little longer than the sound one.

The above cases may be regarded as types of most, if not all, of the forms of anomalous dislocations of the hip-joint. The symptoms are usually prominent, if not positively characteristic. The treatment must be conducted according to the general principles which guide the surgeon in the management of the ordinary varieties of the accident. Manipulation alone will frequently suffice to effect reduction, as there is always necessarily extensive rupture of the soft parts; when greater force is required, the pulleys must be employed. In some of the cases here mentioned, the restoration was effected by a kind of compound process, the dislocation being first changed into a common one, from which the head of the bone was afterwards returned to its natural position by a secondary effort.

PARTIAL AND COMPLICATED DISLOCATIONS.

The possibility of a partial dislocation of the hip-joint is still a debated point. Malgaigne admits the possibility, and adduces cases in illustration of it. Professor Hamilton thinks he has met with two examples of it; and, many years ago, Dr. J. C. Warren saw one, in a child six years old, which has also been referred to this class of injuries. If we define, as in strictness of language we must, a partial dislocation to be one in which the articular surfaces of this joint still partly retain their natural relations, it is extremely questionable whether such an occurrence is possible, as a purely traumatic accident; as a result of disease of the head of the femur, of the borders of the acetabulum, or of the ilio-femoral ligaments, it is easy enough to admit it.

Subluxation of the femur is an occasional occurrence; a lesion in which the person possesses the faculty of voluntarily throwing the head of the femur out of place, and at the same time of reducing it by his own unaided efforts. A considerable number of such cases are upon record. Portal was, perhaps, the earliest writer to draw attention to it. The accident has hitherto been noticed chiefly in young and middle aged men, very few instances having been observed in women. The most common form of the dislocation is the iliac. The affection in some instances is congenital; in others it has evidently been the result of external injury, and in all it is accompanied by more or less relaxation of the ligaments. A few years ago a contortionist exhibited himself in this city, who could voluntarily dislocate nearly all the movable articulations in his body. Many of the subjects of this affection are more than ordinarily muscular. It does not seem that such cases require any surgical treatment or mechanical support.

Dislocations of the hip-joint are sometimes complicated with fracture of the femur; the occurrence, however, is very uncommon, and is chiefly of interest in reference to the restoration of the parts, which should always, if possible, be effected by manipulation instead of by extension and counterextension. Dr. James Douglas has reported a case of luxation upon the pubes accompanied with fracture of the neck of the femur, the superior extremity of which was found after death, twelve years after the receipt of the injury, in the groin, on the inside of the femoral vessels. The head of the bone still remained in its unnatural position. The reduction of such a dislocation must necessarily, one would suppose, be attended with immense difficulty, and yet it would seem, from experiments performed by Richet upon the dead subject, that this is not the fact. He ascertained that, by luxating the femur and then dividing the neck of the bone, so as to imitate a fracture, he could easily push the head into its socket. When the femur is broken in its shaft, the limb, as a preliminary step, must be firmly put up in splints, otherwise it will be impossible to obtain a proper leverage for executing the requisite manipulations. Examples of successful reduction under such circumstances have been reported by different observers, among others by Bloxam, Birket, Eténe, and Oscar Allis.

Dislocations of the hip-joint, complicated with fracture of the acetabulum, are always serious accidents. Cases occur in which the head of the bone is pushed through the bottom of this cavity into the pelvis, inflicting great, if not fatal, injury upon its contents; and specimens are to be seen in different museums, where the floor of the acetabulum was broken into numerous fragments by violence sustained in this way. The rim of the acetabulum is occasionally chipped off by the head of the femur, especially in the iliac and sciatic forms of luxation, and, in such an event, it is always very difficult, if not impossible, to retain the parts in their natural relations after replacement. The best plan, after reduction, is to keep up permanent extension by means of a weight attached to the foot, and to support the affected joint with a broad belt passed around the pelvis.

Severe injury is sometimes inflicted upon the sciatic nerves, as in the sciatic form of dislocation, by the pressure of the head of the femur. In such an event there must necessarily be more or less numbness in the corresponding limb, occasionally attended with partial paralysis. In a case observed by Mr. Hutchinson, of London, the paralysis was permanent.

CHRONIC DISLOCATIONS.

Chronic dislocations of the hip-joint are occasionally brought under the observation of the surgeon, and the question, therefore, necessarily arises, when should such displacements be considered as irreducible? It has been seen elsewhere that Sir Astley Cooper asserts that, as a general rule, it is imprudent to attempt restoration after the eighth week, except in persons of a debilitated frame, or very lax habit of body; and most English and American surgeons, adopting this view, have inculcated similar precepts. I believe this

opinion to be in the main correct, and it may even be assumed that there are not a few cases which will resist all efforts at reduction long before the expiration of this period. In an especial manner is this true of the dislocations backwards into the sciatic notch and downwards into the thyroid foramen, in which the head of the femur becomes much sooner firmly and immovably fixed in its new position than in the iliac and pubic varieties. Sir Astley Cooper himself admits the existence of exceptions, and he has published the particulars of a case of luxation, upon the dorsum of the ilium, reduced after the lapse of five years. Numerous instances of a similar purport, only of much shorter duration, have been narrated by other writers, all tending to show that there are circumstances in which reduction may be hoped for after a joint has been out of place for several months.

It is not necessary to repeat here what has elsewhere been insisted upon in regard to the considerations which should influence the surgeon in the choice of his cases; or, in other words, the circumstances which should induce him to attempt or decline interference. Full instruction has already been given upon this subject, and yet, in view of its paramount importance, it may not be amiss to subjoin a few remarks, if it be only for the purpose of insuring greater care and caution.

The circumstances which may usually be considered as forbidding any efforts at restoration are, first, the absence of mobility in the luxated bone; secondly, occlusion of the acetabulum by fibrinous deposits; and, thirdly, great disorder of the general health, rendering it probable that the system could not withstand the shock and irritation following the operation.

The first of these points can usually be determined by moving the limb about in different directions, and watching the degree of displacement suffered by the femur. The examination should be conducted by taking hold of the knee, or, better still, of the knee and ankle, and it will be most efficient if while the limb is rotated, or attempted to be rotated, the hand be applied to the head of the luxated femur. When there is no motion, or motion only in a limited degree, it may be assumed that the adhesions are too strong to admit of rupture without risk of serious injury to the parts.

It is not always, indeed not generally, easy to determine whether the acetabulum has been filled up or not by plastic deposits. The probability of such an occurrence may be inferred if the accident have been followed by severe inflammatory action, if the parts have ceased to be tender on pressure, and if the head of the bone have contracted firm adhesions to the surrounding tissues. If any doubt remain, the exploring needle might be used, its point being carried about in different directions, to ascertain the amount and consistence of the obstructing substance.

It may be stated that, other things being equal, the acetabulum will be filled up much sooner in young, robust subjects than in the aged and feeble, and that, as a general rule, the likelihood of its being so is always in proportion to the length of time that has elapsed since the occurrence of the displacement.

Finally, the patient's health may be so much reduced as imperatively to prohibit all attempts at reduction, not on account of any pain that might be experienced, for chloroform would effectually prevent that, but because so much violence might be done in the operation as to cause the most intense inflammation and constitutional irritation, placing life in imminent peril.

When it is deemed advisable to undertake the treatment of such cases, it will generally be necessary to use the pulleys, subject to the rules and regulations already laid down for their employment; but sometimes the object may be readily be attained, or at all events, without much difficulty, simply by manipulation. Thus, Dr. Dupierris, of Havana, and Dr. Blackman, of Cincinnati, each met with an instance of iliac luxation of six months' standing, in which they succeeded most satisfactorily by this method alone; and a number of similar cases have occurred in the practice of other surgeons. Dr. Sayre effected the reduction of a sciatic luxation by manipulation at the end of nine months; and Dr. Smyth, of New Orleans, was equally fortunate in a case of the iliac form of the accident at the end of this period. Such examples are full of instruction, and deserving of the most attentive consideration, conveying, as they do, a highly valuable practical lesson. Nevertheless, they must be regarded merely as so many exceptions to a general rule, and nothing more.

Finally, instances have occurred, as those observed by Physick, Travers, Randolph, Malgaigne, Blackman, Wood, and Prince, in which, in an attempt to reduce an old dislocation of the hip-joint, the femur gave way at its neck, within the capsular ligament. Sometimes violent inflammation, abscess, pyæmia, and death, have followed the accident. Occasionally a more fortunate result ensues, the fracture of the bone being eventu-

ally succeeded by a good use of the limb, as in the case of a man between thirty-five and forty years of age, whom I attended along with a former colleague, Professor Joseph Pancoast. The head of the femur lay upon the iliac bone, the displacement having occurred nearly three months previously. There was great lameness, accompanied with much deformity, and, as the patient was very anxious for relief, he was accordingly anæsthetized and subjected to the use of the pulleys, as well as to manipulation. During the progress of our efforts, the bone suddenly broke at its neck, with the result of a very good use of the limb, the patient being able in a few weeks to move it in every direction, instead of being obliged to hold it in the stiff and unseemly position which it had been previously. The shortening did not exceed two inches.

Although it might not be advisable to adopt such a procedure as this as a rule of practice, it is worthy of consideration whether, in cases of irreducible dislocations, attended with great deformity, and a useless condition of the limb, it would not be proper. The patient here alluded to experienced no serious inconvenience from the accident, and the result was certainly highly gratifying. It is to be borne in mind that, from the softening which the articular extremities of the bones undergo in old and neglected luxations, such a fracture is a comparatively easy and simple occurrence, not necessarily followed by severe inflammation. Without such an effort, it is evident that the patient must remain a cripple for life. Instead of fracturing the neck of the bone, however, a safer and better plan is to divide it subcutaneously with an Adams's saw. A case of old irreducible thyroid dislocation, in which the head of the femur was excised, has been reported by MacCormac, of London.

CONGENITAL DISLOCATIONS.

Congenital luxation of the hip-joint is very uncommon. Females are more liable to it than males, and it is also more frequent in scrofulous than in healthy children. Of 107 cases reported by Pravaz, in 1884, only 11 were males. Of these cases 51 were double; the right hip alone was affected in 28, and the left in 24. The immediate causes of this variety of displacement are, first, shortness, total absence, or extreme obliquity of the neck of the thigh-bone; secondly, partial or entire obliteration of the cotyloid cavity; and, thirdly, deficiency, extraordinary elongation, or complete absence of the round ligament. The capsular ligament is frequently elongated and relaxed, and the head of the femur is occasionally materially diminished in size.

The malformation consists in shortening of the affected limb, unnatural projection of the great trochanter, ascent of the head of the femur into the iliac fossa, inversion of the leg, and obliquity of the pelvis. The motions of the joint, particularly those of abduction and rotation, are constrained and imperfect; the muscles of the upper part of the thigh are retracted, or drawn towards the iliac crest; the limb is thin, wasted, and out of all proportion to the rest of the body; the tuberosity of the ischium is almost uncovered, and, consequently, unusually prominent; the upper part of the trunk is thrown backwards, while the lumbar portion of the spine projects forwards, being concave behind; the pubes is placed almost horizontally on the thighs; and the ball of the foot alone touches the ground when the child stands erect.

In the recumbent posture, when the weight of the trunk is taken off, and the muscles are relaxed, most of the symptoms of luxations disappear, and the limb may be shortened or elongated at pleasure. In walking, the body is inclined towards the sound side, and the head of the dislocated bone sinks towards the cotyloid cavity by its own weight. As age advances, the limb becomes shorter, the femur ascending higher and higher on the ilium; the obliquity of the pelvis augments; and the power of locomotion, already so much impaired, is completely destroyed.

Congenital dislocation of the hip-joint may generally be easily distinguished from other accidents or maladies, by the affection being observed at or soon after birth; by the obliquity of one or both thighs; by the absence of pain, swelling, and ulceration; and by the head of the femur being displaced without any external violence; and by the ability of the surgeon to lengthen or shorten the limb at pleasure. In disease of the hip there is always more or less pain, with a feverish state of the system, and gradual failure of the strength; the parts about the joint are tense and swollen; the limb, at first somewhat lengthened, becomes afterwards shortened, and cannot be extended without the greatest suffering; and the motions of the ilio-femoral articulation are permanently impaired.

The pathological appearances vary. In general, the cotyloid cavity is partially obliterated, or entirely deficient, being replaced by a small, irregular osseous prominence, de-

void of cartilage and synovial membrane; the head of the femur, often flattened at its antero-internal aspect, rests in a kind of superficial fossa on the dorsal surface of the ilium; the round ligament is elongated, partially worn away, or even altogether absent; and the surrounding muscles are either atrophied, transformed into a yellowish, fatty, fibrous tissue, or preternaturally developed. In the latter case, their action is preserved; in the former, it is very much restricted, if not totally abolished.

The *treatment* of congenital dislocation of the hip-joint can seldom be anything more than palliative. In cases of recent standing, permanent extension, by means of a common fracture apparatus, or some other suitable contrivance, may be tried with a prospect of advantage. When both joints are involved, the patient should be kept for a long time in the recumbent posture, in order to take off the weight of the body from the limbs, as this is the main agent in aggravating the displacement. As an important auxiliary measure, the shower-bath, followed by dry friction, or friction with ammoniated and other stimulating liniments, may be employed. The pelvis may be encircled with a broad, well-padded belt, so as to steady the trochanters, and counteract the tendency of the thigh-bones to ascend towards the iliac crests. If debility exist, tonics will be required, especially quinine and some of the preparations of iron.

Mr. Broadhurst, of London, recently, in a case of this kind, divided all the muscles that are inserted into the great trochanter, brought down the limb, and held it in this position for six weeks, at the end of which the patient was able to walk without the aid of artificial support. All attempts to create a new socket for the displaced bones must be futile, notwithstanding what has been said to the contrary.

END OF VOL. I.
